In a review of the literature Sacks (1937) found only 64 cases published up to that time; by the beginning of 1940 these had reached a total of 70 (Carey, 1940). All the cases show a striking similarity, the patient usually being a child aged 2 to 15 months, who becomes suddenly ill and dies often in less than 24 hours. A haemorrhagic rash of greater or less extent is present in every case, the temperature is mostly between 100° and 103°, and the sudden collapse, cyanosis, and accelerated respiratory rate may lead to a diagnosis of pneumonia. The illness is so fulminating and death occurs so early that complete investigation is generally not possible. The accepted view appears to be that the purpura and the haemorrhage into the adrenals are due to a massive bacteriaemia, and Maclagan and Cooke (1916) suggest a selective action by the meningococcus. If that is so the disease is so fulminating that the patients appear to succumb to the general infection before the lesions of the meninges have had time to develop. It might, of course, be a fulminating type of any other infectious fever.

THE ADOLESCENT CRIMINAL

The Adolescent Criminal A Medico-Sociological Study of 4,000 Male Adolescents. By W Norwood East, M D., F R.C P , in collaboration with Percy Stocks, M D , D P H., and H T. P. Young, M B. (Pp. 327 45s) London: J. & A Churchill 1942

The social problem of crime calls urgently for first-class scientific research, because effective action is more likely to be based upon precise knowledge than upon unaided insight, however sympathetic. Dr. Norwood East has very long experience of prison administration and of the investigation of criminals; he is also an exceptionally clear and vigorous thinker, an untiring worker, and a good writer. Encouraged by the Home Office, he acted as the director of a team of medical officers, statisticians, and women visitors, and this book is the distilled result of the very copious material they collected from a study of 4,000 male adolescents in prison and in Borstal. The information included data on heredity and family, conditions of home, school and employment, physical and mental defect and disease, personality traits, and the disposal of the offenders and their reaction to treatment. The findings have been made easily available to those who will in the future undertake much-needed reforms of law and practice.

A significant number of youths who were convicted more than once for offences against property had a criminal heredity, which was probably a causative factor in their repetition of the offence. Immoral heredity and quarrelsomeness in the father contributed in a certain number of cases to convictions after the first. Dr. Norwood East emphasizes the need for research into the fundamental problems of inheritance. Physical disease does not appear to be associated with crime, except that cardiac or pulmonary disease in the father sometimes deters a first offender from committing a second offence. Home life was proved to be very important. Boys who had lived continuously with their parents rarely had a long record of previous convictions; those who had lived independently showed an excessive frequency of them. The absence of one or both parents, especially of the father, of a lad over 14 was often associated with multiple offences against property or the person. Those under lax, careless, or repressive control, and those who were intolerant of apparently judicious control, had a relatively greater tendency to repeat criminal offences. The average size of the family when young offenders were 14 years of age was relatively large, but the offender's position in the family did not seem to be important. Multiple convictions for non-sexual offences were significantly associated with residence in a poor district; those for sexual offences had a contrary association, and sexual offenders tended to come from dwellings with a smaller number of inhabitants than did offenders in other groups.

Dr. Norwood East stresses the practical importance of these results, for they suggest that the reactions of adolescents to home conditions are far from being simple or stereotyped, and require further elucidation. A lack of interest in school work and periods of unemployment were significantly associated with multiple convictions, and he thinks that the association of rapidity of growth with frequency of crime is worth further study. The psychological investigation emphasized the need for accurate and early mental diagnosis in the prevention of crime. Research into instinctive activities and perversions in non-sexual as well as sexual conduct associated with crime is, Dr. Norwood East considers, overdue. It may show, for example, that perverse aggressive and acquisitive conduct varies in form and causation, and is based upon a special type of personality largely unaffected by ordinary penal methods. In short, he has demonstrated the need for further research into normal as well as abnormal offenders, preferably in a special institution of the kind recommended by himself and Dr. W. H. de B. Hubert in an earlier report.

The volume is large but light and easy to handle; its print is clean and its tables well arranged. It is the most important contribution that has been made to the criminology of the juvenile male for several years, and should play a great part in solving an increasingly dangerous problem.

PRACTICAL BACTERIOLOGY

Handbook of Practical Bacteriology · A Guide to Bacteriological Laboratory Work. By T J. Mackie, M.D , D P H , and J. E. McCartney, M D , D Sc. Sixth edition (Pp 675 17s. 6d., plus 7d postage.) Edinburgh. E. and S Livingstone. 1942.

Since its original publication in 1925, further editions of Mackie and McCartney's *Handbook of Practical Bacteriology* have appeared at regular intervals, and the sixth is now available. This has been brought up to date by numerous additions to the text, and finally by an appendix describing several new culture media, methods for the bacteriological examination of air, and a discussion of the mode of action of sulphonamide compounds with a note on the use of media containing *p*-aminobenzoic acid for cultivating susceptible bacteria from cases under treatment by these drugs For its size this work contains a remarkable amount of information on bacteriological methods: few similar textbooks contain, for instance, a table of opacity equivalents for estimating the density of bacterial suspensions, probability tables for calculating the numbers of coliform bacilli in water, complete instructions for performing a Rideal-Walker test, or a section on the uses of different types of centrifuge. Although the needs of several types of reader have been kept in mind, those of the professional bacteriologist and technician engaged in routine diagnostic work have received most consideration. To them the condensed and detailed technical information can be of daily service, but the medical student needs less of this and a good deal more of the theory of the subject as applied to medicine. He would also be grateful for illustrations, of which there are none, excepting a few line drawings of apparatus. Modern nomenclature is still relegated to brackets, and generic distinctions are disregarded in the arrangement of chapters, some of which deal with an assortment of quite unrelated micro-organisms. The practical value of this book is of course enhanced by its being the official guide to a system of laboratory supply devised by one of the authors for the L.C.C. laboratory service, but now extended over a much wider field.

MENTAL PROCESSES OF THE SCHIZOPHRENIC

Conceptual Thinking in Schizophrenia By Eugenia Hanfmann, Ph.D., and Jacob Kasanin, M.D. Nervous and Mental Disease Monographs, No 67. (Pp. 115 $2 50) New York. Nervous and Mental Disease Publishing Company 64, West 56th Street 1942

Disorder of the thinking processes has long been noticed clinically in schizophrenia, and by some authorities it is held to be a primary symptom of the disease and one which to a greater or lesser degree is invariably present. There has been much debate on this topic, as clinicians who regard the disease as a response to environmental stress are concerned to minimize the importance of this rather "organic" type of symptom. There has been as much dispute about the nature of the disorder of thought when it does occur. Students of genetic psychology have likened the mental processes of the schizophrenic to those of primitive peoples and to those of children; psychiatrists of a neurological turn, to those seen in aphasia and agnosia. But most authors are agreed that the disturbance is distinct in kind from anything seen elsewhere, and there has been much experimentation in the effort to analyse its nature.

Hanfmann and Kasanin carried out an interesting experiment in which coloured blocks were given to three series of subjects —schizophrenic, organic, and normal. These blocks were of a number of strikingly different shapes and colours, and also were either large or small, and flat or high. The subjects were required to arrange the blocks into four groups, the only possible arrangement being one in which colour and shape were neglected for the other two characteristics. Various levels of performance were possible, and the differences between the groups were analysed accordingly. One of the ways in which the schizophrenic differed qualitatively from the normal and the organic subject was in an inability to see the nature of the solution even when it had been actually found. But it was discovered that a conceptual—i.e., insight-ful—approach was confined to the groups both of normals and of schizophrenics who had had a college or higher education; and in general the authors do not seem to have done enough to equalize the highly important factor of intelligence in their three groups. The group of schizophrenics who had had a college education was controlled by a group of research assistants of, no doubt, very high intelligence, and the resulting comparison does not seem to be an entirely fair one.

Notes on Books

PINEY and WYARD'S *Clinical Atlas of Blood Diseases* (J. and A. Churchill, 16s.) is so popular with students and housemen that we are not surprised to receive a copy of a fifth edition. It is both the virtue and the fault of the book that it is a collector's handbook, and a few new specimens have been added without any rearrangement of the collection such as most haematologists would feel was overdue. The additional plates are not so good as the old and do less than justice to the results obtained by sternal puncture.

In its fifth edition Major H. H. CLAY'S *Sanitary Inspector's Handbook* (H. K. Lewis and Co., 18s.) has been revised in the light of recent progress. Account is taken of the far-reaching influence of present-day war conditions upon the range and relative importance of the sanitary inspector's duties. Emergency enactments brought into being to meet the needs of the hour are for the most part passed over in silence, but attention is properly directed to any statutory changes which promise to be more permanent. The fifth edition may be commended as timely and reliable. In these and other respects it maintains the high standards of its predecessors.

The American book by Helen Clapesattle, entitled *The Doctors Mayo*, which was reviewed in our issue of March 28 (p. 415), is now published in this country by the Oxford University Press at 22s. 6d.

Preparations and Appliances

AN APPARATUS TO MEASURE MUSCLE RECOVERY AND RANGE OF JOINT MOVEMENT

Mr. G. A. POLLOCK, F.R.C.S.Ed., and Mr. GEORGE BROOKS write from the Wilkie Surgical Research Laboratory, University of Edinburgh:

An accurate estimation of the degree of functional recovery from an injury is of importance to the surgeon, the physical therapist, and the insurance assessor, especially when injury has been done to the nerves, the muscles, or the joints of the hand. A patient who does not see proof of his progress under treatment may become disgruntled and uncooperative. Instead of continuing with enthusiasm at his exercises, massage, or occupational therapy, he becomes irregular in his attendances and finally ceases to appear for treatment. If there was some device by which one could estimate the rate and degree of progress under treatment, and at the same time demonstrate this to the patient, he would be stimulated to redoubled effort.

With this object in view we devised a dynamometer. The apparatus consists of an oblong box, the form and dimensions of which are shown in the diagrams. It carries an upright post, A, from which the spring balance B is suspended. By means of a system of light vulcanite pulleys, C and D, one of which acts on the pivot E, the excursions of the finger plate and finger rest F and G are registered on the spring balance B in grammes of pull. The range of movement of F and G can be read also in degrees on the protractor scales H and I. By means of this additional check a greater degree of accuracy can be obtained when individual joint movements are compared from time to time during treatment.

The finger-plate attachment J is fitted to the apparatus at 1 or 2, depending on whether it is the distal or proximal interphalangeal joint that is being examined. With the finger-plate attachment in position at 1 or 2, the strength of the flexor digitorum profundus and of the flexor digitorum sublimis is estimated by noting the position of the indicator of the spring balance B. If the finger-plate attachment is fixed at 3, not only the strength of the pull in grammes but also the range in degrees can be read on the scales of B and H. Estimates of the strength and range of abduction or adduction of the fingers to or from the middle line can be made by fitting the finger rest to the apparatus at the pivot hole K. The finger rest is slightly higher than the level of the box itself, and it is inclined forwards. Thus the finger is slightly hyperextended at the metacarpophalangeal joint to eliminate the action of the extensor tendon so that a more accurate appraisal of the power of the interossei and lumbrical muscles may be obtained.

Friction is partially reduced during the performance of those movements by the movable roller of the finger-rest and the pivoting of the pulley wheel at E. The power of these movements can be read off also on the scale B, and their excursion described in degrees of movement by reference to the protractor scale I.

ACUTE ASEPTIC MENINGITIS

Up till 1925 confusion was present in the description of various cases of meningitis, apart from syphilitic and tuberculous meningitis, in which the cerebrospinal fluid was bacteriologically sterile and contained an increased number of mononuclear cells. At that time Wallgren[1] brought clarity to the situation by gathering a number of them into a symptom-complex of unknown aetiology which he termed "acute aseptic meningitis." All these cases had an acute onset, fever, and symptoms of meningeal irritation, and recovered completely after a short illness. Since then three viruses which give rise to the clinical picture of acute aseptic meningitis have been isolated. The most common of these is that of lymphocytic choriomeningitis, which has been found in U.S.A., Great Britain, France, and Japan. The virus of swineherd's disease (Durand *et al.*[2]) also produces this picture, but is found only in neighbouring areas of France, Switzerland, and Italy. Lastly, there is the virus of pseudo-lymphocytic choriomeningitis (MacCallum *et al.*[3]), which has been isolated on only two occasions, both in England. These three viruses provide only about one-third of the cases of acute aseptic meningitis; the remainder are of as yet unknown aetiology.

Lymphocytic choriomeningitis appears to be much more frequent in the United States than in any other country, possibly because it has been more intensively and extensively studied there. The virus was first isolated in 1934 by Armstrong and Lillie[4] in the U.S.A., and since that time 36 proved cases of the meningeal form, including three of the encephalomyelitic type, and one proved and one probable case of systemic infection without meningeal involvement, have been reported. In addition, examination of sera showed neutralizing antibodies in 32% of 58 cases diagnosed as aseptic meningitis, 28% of 106 cases with recent influenza-like illness but no signs of meningeal irritation, and 10% of 1,000 individuals chosen at random who gave no history of any involvement of the central nervous system (Wooley *et al.*[5]). In this country there have only been 5 reported isolations of the virus from human beings, and neutralization tests on suspected cases have shown a very small proportion of positives. The high percentage of positive sera from individuals showing no obvious involvement of the C.N.S. indicates that there is no single clinical picture which can be said to include all cases of infection with the virus. However, there are certain indications that may lead one to differentiate between a typical case of lymphocytic choriomeningitis with meningitic symptoms and one of acute aseptic meningitis of unknown origin as described by Wallgren. In a group of 23 proved virus cases Baird and Rivers[6] found 16 gave a history of an influenza-like precursory illness which lasted from one to three weeks before the onset of meningitis. Contrasting with these, in a group of 18 patients with meningitis of unknown cause, there were only 3 who had a prodromal illness.

Following the injection of infective mouse brain into human beings (Lepine *et al.*[7]) fever develops in one and a half to three days, and the virus is present in the blood usually from then till the onset of meningitis. The prodromal symptoms develop five to ten days after exposure to the virus and are of one to three weeks' duration. Fever, ranging from 100° to 103° F., usually occurs in two or three waves, with a remission before the onset of meningitis. Then comes an acute onset of fever and chills, generalized headache, and nausea and vomiting. There may be lumbar backache, drowsiness, and disorientation. On physical examination the usual signs of meningitis are present in varying degrees. The blood counts are as a rule normal during this stage, but virus may occasionally be detected in the first few days of meningitis. The cerebrospinal fluid is usually clear or slightly turbid, and rarely shows a fibrin clot on standing. The pressure may be normal or increased. The cell count has varied from 63 to 3,200 per c.mm., with the average about 600 to 1,000, of which 95 to 100% are usually lymphocytes. The sugar and chloride content are usually normal, though both may be reduced. The protein may be normal, but is usually elevated to 50 to 200 mg. per 100 c.cm. of fluid. The virus can be isolated from the cerebrospinal fluid during the first 7 to 10 days of meningitis, but then as a rule disappears. A positive complement-fixation reaction with the blood commonly appears 3 to 4 weeks after the onset and disappears in 4 to 6 months, in contrast to neutralization, which does not appear for 6 to 8 weeks and lasts much longer. An excellent description and detailed study of a typical case is included by Farmer and Janeway[8] in their complete review. In this, the most recently reported case, the patient, a girl of 21, removed a dead mouse from a trap. Three days later she began to feel listless, had occasional spells of light-headedness, and looked unwell. On the fourteenth day she visited her doctor, who found her temperature was 101° F. (oral) and that she had lost 8 lb. in weight in the past month. Though weak, she was able to continue her studies till the twentieth day, when she developed headache, stiffness of the neck, nausea and vomiting, loss of appetite, drowsiness, and lumbar backache. The virus was isolated from her spinal fluid on the twenty-seventh and thirty-fifth days of the illness. However, for every such typical case there must be very many with only a few influenza-like symptoms and no signs of central nervous system involvement. A very good example of such an illness was that described by Armstrong and Hornibrook[9] as the result of an accidental laboratory infection. The patient was carrying out research on the virus and constantly handling infected mice. There was no circumstance which might indicate the possible incubation period of the disease. His first symptoms were troublesome pains in his arms, shoulders, and back, with an accompanying temperature of 99.4° F. By the following day he had lost his appetite and the lumbar pain had increased. The fever lasted five or six days. The acute illness lasted only a week, but weakness and prostration persisted through the following week. There were no symptoms or signs of involvement of the nervous system. A white blood count on the fifth day of illness revealed leucopenia of 2,900 cells. The virus of lymphocytic choriomeningitis was isolated from the blood on the fifth day of fever, and his serum, which had been negative, gave strong protection against the virus six weeks after the illness.

The source of infection and portal of entry of the virus in man has not been settled as yet. However, the weight of evidence at hand indicates the grey mouse (*Mus musculus*) as the reservoir in the naturally occurring disease. Armstrong and his colleagues[10] have found a much greater percentage of infected and immune mice among those caught in the houses where cases have occurred than among mice from homes where the illness has not been present. Experiments carried out over 4 years by Traub[11] in a stock of white mice, and those of Haas,[12] also in white mice, indicate that mice infected *in utero* probably transmit the infection to their offspring and contacts by their nasal secretions. However, their urine, faeces, and semen also contain active virus, which may be the source of infection for human beings. Seven naturally infected house mice trapped in Washington showed no symptoms during five months' observation, but transmitted the infection to normal white mice placed in the cage with them. These latter also showed no symptoms, but virus was present in their blood. In the case of Farmer and Janeway[8] the virus was isolated not only from a mouse found in the fourth-floor flat of the patient but also from the embryos of a pregnant mouse trapped in the cellar of the same building. The virus has been shown experimentally to infect by penetrating the unbroken skin of the guinea-pig, which suggests this as the portal of entry in those who handle infected mice without gloves. The virus may be present in the dust where infected mice have been and infection may take place by the nasal route. But in man the virus has been isolated only once from the nasopharynx, and in that instance the patient was never shown to have developed immune bodies, so proof that the virus was of human origin is lacking. Dogs, both in America (Dalldorf[13]) and England (Findlay *et al.*[14]), also have been shown to harbour the virus in their spleen, and an inoculated dog transmits the infection to his cagemate. Farmer and Janeway[8] describe a case in which a dog might have been the source of infection. Strangely enough, there is no indication that cats are infected or carry the virus.

The most likely disease with which trouble in diagnosis may arise is tuberculous meningitis. Very little difference may be noted till the latter suddenly enters the terminal stage and is fatal. The web-like clot which usually forms on standing is a good point of differentiation. The sugar content is usually decreased below 45 mg. and the chloride content below 650 mg. per 100 c.cm., but normal findings should not be taken as ruling out tuberculous meningitis. The percentage of lymphocytes in the cerebrospinal fluid rarely rises above 80. Also the blood sedimentation rate is elevated. If proof is desired of the virus aetiology of a case two courses may be followed. Inject 5 to 10 c.cm. of blood intraperitoneally in a guinea-pig in the pre-meningitic phase and the same amount of cerebrospinal fluid in the stage of meningitis. Elevation of the temperature to 104° F. (per rectum) for one or two days probably indicates infection; and the spleen and/or brain should be removed aseptically, placed in 50% glycerin in saline, and stored in the ice-box till sent to a laboratory for identification. Serum taken in the acute and convalescent (fifth to sixth week) stages can be examined for immune bodies to lymphocytic choriomeningitis virus.

EXPERIMENTAL SHOCK AND THE "CRUSH SYNDROME"

Since the crush syndrome was first recognized as of common occurrence after air raids, the treatment of it has been the subject of much speculation. The chief reason for this is lack of knowledge of its pathogenesis. According to one school of thought, summarized in a recent discussion at the Royal Society of Medicine,[1] shock and renal damage are two aspects of the same primary lesion —muscle necrosis—although their obvious results are separated in time by seven days: the shock is due to plasma leaving the blood stream and entering the injured area, and the renal damage due to substances such as myohaemoglobin and acid metabolites leaving the damaged area and entering the general circulation as soon as the local blood supply is re-established. On this view the first line of treatment is to establish an alkaline diuresis along the lines shown by Baker and Dodds[2] in 1924 to be effective in protecting animals from the renal effects of intravascular haemolysis; later, to combat shock. Another view, put forward by Patey and Robertson,[3] is that the condition, including its renal manifestations, is the result not of toxic bodies liberated from damaged muscles but simply of the loss of blood constituents into the injured limb. They accordingly treated two cases by an inflatable rubber cuff designed to prevent or diminish the local oedema; whether it had any effect other than this is rather doubtful, as treatment in the first case was started during recovery (11th day), and the second case, treated from the first day, showed no evidence of shock or renal damage except red cells and some albumin in the urine.

Recent experimental work by Duncan and Blalock from the Johns Hopkins Hospital[4] has shown conclusively that the severity of a similar type of shock produced by a crushing clamp may be modified by subjecting the damaged limb to a pressure of 40 mm. Hg in a pneumatic cuff. As, however, the treated animals which survived shock were killed before renal failure could become fatal, and as there is no record of a rise of non-protein nitrogen in the treated group, to compare with that of the untreated group, these experiments offer no ground for deductions as to the effect of pressure therapy on renal damage. To apply the results of these experiments directly to man and to advocate, as was suggested recently in these columns by Patey and Robertson,[5] routine use of such a method throughout the country may be unwise. In our present issue they give clear instructions how to apply a bandage so as to exert a pressure of about 40 to 60 mm. Hg on a limb. It appears possible from the dog experiment that a tight bandage or a pneumatic cuff will limit plasma transudation and thus the degree of shock due to such plasma loss. The oedema, however, is only symptomatic of muscle necrosis and, if plasma loss be made good, is eventually absorbed. Considering how often in such crush cases there is diminution of peripheral pulsation or actual gangrene, some anxiety might legitimately be felt about this method of preventing shock, because in inexpert hands the bandage is easily applied too tightly. The use of serum and plasma is a more generally applicable way of combating the shock of crushing injury, at all events until well-controlled observations have shown in man whether the pneumatic-cuff procedure is beneficial or not. If the renal damage is due to substances absorbed from the damaged area, as appears possible, the effect of a pressure cuff, if applied with alternate positive and negative pressures, may be to hasten absorption from the damaged area. On the other hand, a pressure adequate to diminish the reactive hyperaemia seen surrounding a necrotic area may delay absorption of such products long enough either for a natural re-establishment of normal capillary impermeability or for a therapeutic protection of the kidneys by alkali. The possible use, for such a purpose, of a tourniquet for a short time has already been proposed.[1]

[2] *Brit. J. exp. Path.*, 1925, **6**, 247.
[3] *Lancet*, 1941, **1**, 780.
[4] *Ann Surg*, 1942, **115**, 684
[5] *British Medical Journal*, 1942, **2**, 53.

It is clear, therefore, not only from this and previous discussions of the merits of various types of treatment, but also from a review of the published cases, that extreme care must be exercised before claiming any particular type of therapy as effective. To begin with, the possible fallacies inherent in the application of experimental animal results to man are well known. Then, in clinical work, such facts as these must be borne in mind: (*a*) severe cases may occasionally recover without any treatment at all[1]; (*b*) slight cases (one-third of those surveyed[1]) recover without or in spite of treatment; (*c*) other injuries such as haematoma and pressure injuries of nerves closely simulate certain aspects of crush syndrome. It is essential, therefore, in order to ascertain the efficiency of any treatment, to establish criteria by which the severity of the lesion may be estimated. The degree of haemoconcentration and the blood-pressure fall are the most useful criteria of "shock"; the height of the blood urea, the urine output, and the urinary urea concentration have been suggested by Bywaters[1] as the most useful for renal damage. In most cases severity of shock and severity of renal damage seem to run parallel: this has been thought to account for the failure to notice this syndrome in the days when transfusion was in its infancy, as severely shocked patients, untreated, do not survive to show renal failure. Furthermore, the extent of the injury, according to this survey of over 70 cases, appears to determine the severity of both shock and renal damage. These criteria are for the established case; most of them, except the extent of the injury, would be useless if by some means the signs of shock and renal damage could be prevented. Prevention to be effective probably depends on early treatment, certainly as regards shock, and probably as regards renal damage also. The above signs would not therefore be manifest. It may be that the excretion of such products of muscle necrosis as creatine and myohaemoglobin in the urine may turn out to be the criteria of complete success in therapy, together with the later muscle fibrosis. Further experimental studies and careful observation of air-raid victims and the effects of treatment from the very first are both most urgently needed.

RATIONALIZING CHEMOTHERAPY

Sulphonamide chemotherapy passed from the empirical to the rational two years ago with the discovery by Fildes and Woods of the mode of action of sulphanilamide. Their precise disclosure of its point of attack in chemical terms not only settled an acute controversy but opened the door to further developments on more sure and promising lines. What the practical fruits of this discovery may be is now becoming apparent. The action of sulphanilamide on haemolytic streptococci and other bacteria is simply to prevent the utilization of a substance essential for their growth, which is *p*-aminobenzoic acid. Thanks largely to the earlier work of Fildes and his collaborators, various other substances of defined chemical composition, now referred to as essential growth factors, are known to be necessary for the growth of certain pathogenic bacteria. There being a close and simple chemical relationship between *p*-aminobenzoic acid—the growth factor—and sulphanilamide—the growth inhibitor—it can be predicted that a compound having this relationship to another growth factor will inhibit growth by preventing its utilization. Several such inhibitory analogues have in fact been designed and found to function as expected, their relationship to the growth factor being the substitution of $-SO_3H$ or $-SO_2NH_2$ for $-COOH$. The latest product of this form of constructive reasoning, one which may prove to be of great therapeutic importance, is now described by H. McIlwain.[1] Pantothenic acid is an essential growth factor for many pathogenic bacteria, and an analogue which should be inhibitory is pantoyltaurine. This substance, as theoretically predicted, inhibits the growth of bacteria requiring pantothenic acid, including *Str. pyogenes, Pneumococcus,* and some strains of *C. diphtheriae,* and has no effect on the growth of *Bact. coli* and *Proteus vulgaris,* which do not require it. As in experiments with sulphanilamide and *p*-aminobenzoic acid, the presence or absence of growth depends on the relative concentrations of pantoyltaurine and pantothenate; the capacity of various natural fluids such as muscle extract, plasma, and urine, to antagonize the inhibitory action of pantoyltaurine varies with their content of pantothenate. It is an important point that this content in none of the materials tested was such as could prevent the effect of a moderate concentration of pantoyltaurine in the body.

There are other considerations affecting possible therapeutic use. One is the tolerance of the body, and of this it is said that 2.5 g. per kg. body weight can be fed to mice without ill effect. Another is the degree of susceptibility of individual bacterial species; there are variations in this even though the organisms concerned all require pantothenate. To express a further factor which must be taken into account McIlwain proposes the term "antibacterial index" for the ratio between the concentration of the inhibitor and that of the growth factor which it will just antagonize. The antistreptococcal index of sulphanilamide is 25,000, the concentration of this drug necessary to prevent the growth of *S. pyogenes* being this much greater than that of *p*-aminobenzoic acid present in the medium, regardless of the absolute amounts of either. But the antipneumococcal index of pantoyltaurine is 1,000 and the antistreptococcal only 500. Pantoyltaurine is in fact the most effective inhibitory analogue so far studied in this way, as judged by this criterion. Information about its actual therapeutic effect will be awaited with great interest. Meanwhile it may be seen to what elucidation of obscure problems in antiseptic action the fundamental work of the department of bacterial chemistry founded by Fildes is now leading. In another paper McIlwain[2] describes the application of similar methods to an investigation of the apparently more complex action of acriflavine. This is going considerably further than the work of S. D. Rubbo, M. Albert, and M. Maxwell,[3] who have nevertheless by a study of the mono-aminoacridines done much to relate chemical structure with antiseptic and other biological activity. It is not too much to say that the work of Fildes and his colleagues will rank as an achievement at least equal to that of the original discovery of prontosil itself. Domagk's work, although everything else has followed from it, left the whole subject in the darkest theoretical obscurity; that of British workers has made its mechanism plain. The difference between their two methods is that between delving in a lucky dip and constructing to a design.

THERAPEUTIC USES OF CURARE

Sir Walter Raleigh brought the arrow poison of the Aroras from "the large and beautiful land of Guiana" in the sixteenth century, but it was not until 1865 that Claude Bernard showed that its principal action was the paralysis of transmission at the neuromuscular junction. Clinical interest in curare was renewed after the discovery by Bremer in 1927 that small doses, insufficient to paralyse the intact skeletal musculature or to embarrass respiration, selectively released the spasm of decerebrate rigidity. Similarly, West[1] observed a selective response with subparalytic doses in human spastic paralysis, a so-called "lissive effect," which was not present in all samples of curare and was not associated with any known constituent. This variation in the composition of the drug may explain other anomalies in its use as an adjunct in the physiotherapy of spastic paralyses. Thus, whereas Burman[2] noted a selective release of plastic muscular rigidity and spasm, lasting two or three days on intramuscular injection, Bennett[3] found these desirable results far more transient in comparable cases. However, Denhoff and Bradley[4] have confirmed Burman's results on six children with cerebral palsy whom they studied for four months. A standardized stable curare administered intramuscularly gave improved relaxation in the hypertonic muscles for about four days, so that it was necessary to inject their patients only twice weekly. Efficiency combined with safety was attained only when the dosage was determined individually, by noting the responses to increasing doses; the margin of safety is not very large and adequate supervision was required the whole time. On the other hand, when the optimal dose had been found the response was remarkably uniform. Denhoff and Bradley abandoned the intravenous route of administration because of the prevalence of paralytic symptoms, with evidence of respiratory embarrassment. They confirmed previous observations that with large doses the paralysis affects the facial muscles first, followed by relaxation of the neck, trunk, and limbs. During the acute stage there may be pallor and excessive perspiration, confusion, diplopia, and slow shallow respirations. The symptoms may be alarming, but pass off without treatment in 40 minutes, though for the next 24 hours the lethargy is sufficient to interfere with physiotherapy. Von Euler[5] has shown that intracisternal injection of curarine in animals may cause a profound stimulation and even convulsions; although this is hard to equate with the clinical findings, it does suggest that some of the acute symptoms may be due to a central action of curare, an action that is normally overshadowed by the peripheral paralysis. Dangerous symptoms may be averted by injection of prostigmine or adrenaline. The paralytic as opposed to the "lissive" action of curare has been employed in the symptomatic treatment of various convulsive states. Thus curarine has even been used as an intravenous drip, 1/4 mg. per kilo per hour, to prevent the weakness and fatigue which hastens death in tetanus,[1] but the number of recorded cases is not yet sufficient to estimate its value. However, Bennett has used curare to prevent fractures in leptazol shock therapy with considerable success.

The search for curare substitutes has been encouraged by the difficulties in obtaining the drug from the South American witch-doctors. Two types of substitute have been investigated: quaternary ammonium compounds and erythrina derivatives. Quinine methochloride has a curariform action even on oral administration, and Bennett has experienced some success using 3 to 4 grammes daily in eight cases of spastic athetoid paralysis. Erythroidine hydrochloride has also been studied in Parkinsonism and spastic paralyses[6]; the toxic reactions seemed too severe to allow continued trials, although, as they are out of all proportion to those experienced in animal experiments, other derivatives of erythrina may prove more useful.

INCLUSION CONJUNCTIVITIS

Immediately on the publication in 1907 by Halberstaedter and v. Prowazek of the finding of minute bodies in the epithelial cells of the trachomatous conjunctiva the validity of these findings and their specific significance were called in question by many. The issue became more confused when Stargardt in 1909 demonstrated inclusion bodies in various ocular conditions, among them a case of bacteriologically negative ophthalmia neonatorum, and when Haymann observed inclusion bodies in a series of cases of gonococcal ophthalmia neonatorum. It came to be widely believed that inclusion bodies were a reaction product of the epithelial cells to either the organism of trachoma or the gonococcus, but that it itself was not an aetiological factor. Herzog attempted to correlate ophthalmia neonatorum with trachoma by suggesting that trachoma was produced by an evolutionary form of the gonococcus adapted to parasitism on the epithelial cells, whilst Lindner, with more justification, divided ophthalmia neonatorum into two groups—one due to the gonococcus and the other to inclusion bodies, because he found that the bacteriologically negative cases of ophthalmia neonatorum showed these bodies. He linked this inclusion body ophthalmia with trachoma, regarding trachoma as a modified form of genital infection. This was because a macacus and a baboon developed a conjunctivitis indistinguishable clinically from trachoma when inoculated with the vaginal secretion of a mother whose child, shortly before, had been born with inclusion ophthalmia neonatorum. That the inclusion bodies may have been the infective agent was suggested later when Halberstaedter and v. Prowazek found them in the genital epithelium of a mother giving birth to an infant with inclusion blennorrhoea. The unity of trachoma and inclusion ophthalmia neonatorum is still upheld by Lindner, who regards both affections as a manifestation of the same agent; trachoma to him is essentially a genital infection, and inclusion blennorrhoea is the more primitive form of trachoma. Inclusion blennorrhoea, in his terminology, is paratrachoma and has the same relation to trachoma as paratyphoid has to typhoid.

Inclusion conjunctivitis takes several forms, and may appear as a bacteriologically sterile ophthalmia neonatorum, as a mixed infection with a gonococcus and other organisms,[7] or as follicular conjunctivitis in children and adults, particularly in the form of so-called swimming-bath conjunctivitis. These local conditions find a counterpart in a non-specific urethritis in men and cervicitis in women: inclusion bodies are found and the genital infection runs a mild course.[8] The problem of the relation of inclusion conjunctivitis to other virus infections, such as trachoma and lymphogranuloma inguinale, is now much simplified by the clear recognition of these various types. The apparent confusion, which was precipitated by the first description of inclusion cells in ophthalmia neonatorum, has led to a valuable consolidation of our knowledge of ophthalmia neonatorum and of a whole group of follicular reactions in the conjunctiva, as well as a clear recognition of yet another type of venereal disease. The inclusion bodies of trachoma are distinct from those seen in ophthalmia neonatorum and genital infection of the inclusion type.

DOCTOR, AND SOLDIER TOO

BY

T. P. BUIST, M.A., B.Sc., M.B., Ch.B.
Lieut.-Colonel, R.A.M.C.; Chief Instructor, No. 1 Depot, R.A.M.C.

From time to time articles have appeared in this and other journals on various aspects of the life and functions of the Army medical officer. It must be assumed that any prospective R.A.M.C. officer who has access to them will have read these articles, yet it is noticeable that many of the medical officers entering the Services have failed to appreciate that an Army doctor in almost any position must have a working knowledge of various military subjects if he is to function efficiently.

The metamorphosis, for such it is, from civil to military medical practice involves three important changes: (1) a domestic change, from private to communal life; (2) a change of sphere, from work in a relatively simple and static community to work in a complex, disciplined, and essentially nomadic organization; (3) a change in horizon, in that whereas in civil practice the doctor's primary concern was medical care of the sick or hurt, he is now joining a Service in which care of the sick and hurt is ancillary to medical care of the healthy. Although the implications of the first of these changes are generally realized by the prospective medical officer, those of the second are usually only vaguely sensed, and those of the third change seldom appreciated at all.

Functions of the Army Medical Officer

The general functions of the Army M.O. fall in the main into one of the following three groups:

1. *Maintenance and Servicing*.—The typical representative of this group is the regimental medical officer, more formally known as the officer in medical charge of effective troops. His work and responsibilities have been ably described in the articles already referred to (Middleton, 1940; Robinson, 1941; Burges, 1941; Tidy, 1942). Briefly, the R.M.O. is the commanding officer's technical expert in the maintenance of the fighting health of his unit. As such, everything which directly or remotely may affect the health of the officers and men is his concern. If he is to fulfil his function efficiently not only must he be a competent doctor but he must have an adequate knowledge and understanding of the work of the unit he serves.

2. *Salvage*.—Under this heading may be grouped all units whose responsibility is the collection of casualties and their delivery in repairable condition to the repairing units. Its typical representative is the Field Ambulance. The Field Ambulance medical officer must be active, self-reliant, a leader of men, and able to find his way about in unfamiliar territory and amid the complexities of the military formations in battle. He must be a competent soldier as well as a doctor.

3. *Repair and Reconditioning*.—Under this heading come the C.C.S., hospitals of all types, and units responsible for the control of post-hospital convalescence. It should be noted that repair and reconditioning aim at the return of the repairable casualty to full military health as expeditiously as possible. This objective must never be forgotten. Even in this group the medical officer, be he a specialist or not, must possess military knowledge and understanding, if only to enable him to turn out his work in the form most useful to the army he serves.

But there are additional and more personal reasons for his possession of military knowledge. Let us take the case of an officer who has entered the R.A.M.C. as a specialist or graded specialist in, say, anaesthetics. It is understandable that, knowing nothing of the Army, he may tend to assume that his work will be much the same as it was in civil life and that knowledge of such things as map-reading, organization, military law, soldiers' affairs, and so on will not concern him. He may be sent to work in a C.C.S. or a military hospital and spend most of his time in his specialty. But it is unlikely that this will occupy him fully all day or every day, and in a military hospital there are many other duties in which he will be expected to bear his share when he is free. Not a few of them will require military as well as medical knowledge. He may, on the other hand, be sent to join a mobile surgical unit as its anaesthetist, perhaps to replace another who has become a casualty. He may find himself reporting for this duty somewhere in the desert, informed that his unit is at "Point X," 30 miles away, given a truck and a driver, and expected to carry on, perhaps in the dark. If he does not know how to find his way about he is likely to get lost; he may cause his driver and possibly others to lose their lives; and the mobile surgical unit may continue to be short of an anaesthetist. Even the specialist must be a fitted piece in the military machine. If not, he may be a potential spanner in the works.

The Preliminary Course for R.A.M.C. Officers

Doctors share with chaplains a privilege which is at the same time a disadvantage, in that they normally enter the Army as commissioned officers without any previous service or experience in the ranks. All other officers are now commissioned only after a period of service in the ranks followed by training in an O.C.T.U. An untrained newly commissioned medical officer cannot avoid feeling a notable greenhorn in any congregation of officers.

The preliminary course of instruction for R.A.M.C. officers is designed to reduce the acuteness of this disadvantage. It comprises three weeks' training in the officers' wing of one of the R.A.M.C. depots, followed normally by a further week at the Army School of Hygiene. A description of the course at one of these depots has already been published (Cameron, 1942) and may be accepted as typical. During the course the metamorphosis is performed under expert and sympathetic guidance. The domestic change, shared with others at the same stage, becomes less drastic; the change of sphere, with new understanding, comes naturally; the change of horizon begins to develop. The officer emerges from the metamorphosis a fledgeling perhaps but not a self-conscious greenhorn, with a growing instinct of how to find his way about in his new work, with an increasing tactical sense, and feeling and looking fitter physically than he has done for years.

It has been argued repeatedly that it is possible for a doctor to turn himself into a competent Army medical officer without attending a preliminary course of instruction; that, in fact, many have done so; and that such a course is a waste of valuable professional time. An analogous argument can be advanced that it is theoretically possible for a suitably gifted individual to become a competent doctor without attending a medical school. The medicine we practise to-day began with the work of such men. In both cases the process is hard on the aspirant and unfair on the patients. The path is long and rough, and inevitably strewn with unnecessary casualties. That this is so in the case of the Army medical officer, those who have had to start work without a preliminary course are usually the most ready to admit.

Finally, let it be said that the preliminary course is not a cramming course. Its aims are: to define the objects and principles of the medical care and management of soldiers; to give a general picture of the military machine and its medical organization, with close-ups of various aspects of a medical officer's life and work; to teach the new medical officer how to start to find the answer to "What does A do now?" in various circumstances. It is in essence a reconnaissance; and, to quote a well-known military axiom, "time spent in reconnaissance is seldom wasted."

I wish to thank Col. W. Foot, *M.C.*, Commandant, No 1 Depot, R.A.M.C., for permission to submit this article for publication.

It is reported (*Dtsch. Militär arzt*, 1941, **3**) that some 2,102 persons (82%) of the occupants of a camp in Germany were attacked by Flexner dysentery, 20% of them on the first day and the rest in the course of six weeks. The incubation period was three to six days, the illness lasted on the average for two to three weeks, and the death rate was 3 per 1,000 In the first three days the bacteriological demonstration of bacilli was easy, but it was difficult towards the end of the first week, when the stools were slimy and watery. Extensive hygienic measures had to be taken in order to prevent the disease spreading. Treatment with rivanol is stated to have given excellent results.

Reports of Societies

PAEDIATRICS IN MEDICAL PLANNING

The fourteenth annual meeting of the British Paediatric Association, recently held at Windermere, was devoted to a discussion on the future of paediatrics, having in mind the changes in the organization of medical services which will follow the war.

Dr. J. C. **SPENCE** (Newcastle), who opened the discussion, said that three branches of paediatrics had to be planned for—namely, domestic practice, public paediatric services (such as child welfare and school medical care), and, finally, the hospital and institutional treatment of children. To ensure the success of each of these branches it was necessary to have active and progressive teaching units, preferably a hospital or a clinical unit closely associated in a hospital centre with other teaching hospitals and university scientific departments, and providing not fewer than 100 beds, with adequate out-patient and clinic facilities. These should serve as consultation centres for both private practitioners and the public health services. In the interests of both clinical science and the welfare of patients the artificial segregation of patients into medical wards and surgical wards should be abandoned; patients should be re-grouped into clinical units, with wards arranged according to the age of the patients and the character of the disease, and to these units physicians, surgeons, and specialists should be attached. Another problem to which the British Paediatric Association should address itself was the form in which advice and constructive criticism should be given to the Ministry of Health in formulating its paediatric policy. He urged the setting up of an advisory committee—rather than the appointment of a single adviser—membership of which would be limited to a certain term of years.

Children's Nursing

Dr. **ALAN MONCRIEFF** dealt with a memorandum which has been put forward by the London members of the Association. He called attention in particular to the necessity for close co-operation with the health authorities as regards school medical work and child welfare work; to the danger of children's hospitals losing their identity and becoming departments of general teaching hospitals, and to the further danger of the special children's nurses' register being abolished. He said that certain children's hospitals had recently appointed matrons without this diploma. Dr. **REGINALD LIGHTWOOD** said that in London as in other large cities a university centre for paediatrics was certainly needed for postgraduate training, and should be set up without delay. It should have a professor of paediatrics, and the hospital and academic sides of preventive paediatrics should be encouraged. Dr. N. **CAPON** (Liverpool) referred to the shortage of applicants for training as sick children's nurses. This would become even more serious unless something were done to raise the status of such nursing. In his view the problem could not be satisfactorily settled by accepting a short period of service in children's wards as adequate training for paediatric nursing. He suggested that the association should make representations to the General Nursing Council that the register of sick children's nurses should be maintained. Dr. F. M. B. **ALLEN** (Belfast) urged that the interim report recently presented by its committees to the Medical Planning Commission should be carefully studied by paediatricians, and the Commission made acquainted with their views.

State Medicine and Paediatrics

Dr. R. **COLLIS** (Dublin) said that State medicine in effect meant the handing over of the medical profession to become part of the patronage of a central or local authority whose main idea would always be "safety first" or the maintenance of the *status quo*. What was needed was not a nationalized service, but a national medical service through a more complete national health insurance system, including provision for children. What he called "university medicine" should be made the centre of the medical organization, and in paediatrics the Hospital for Sick Children, Great Ormond Street, might well be the centre of paediatric organization, with a chair of paediatrics, the professor, and not the senior physician, holding the predominant position at the hospital. Dr. **WILFRID SHELDON**, while emphasizing the need for a post-war paediatric policy, said that perhaps the more immediate need was the solution of the numerous clinical problems of childhood which the war had created. He thought the association should approach the authorities concerned as an organization prepared to advise on, and assist in, measures to deal with such questions. Dr. C. W. **VINING** hoped that the children at any rate would not be caught up into national health insurance. There should be a comprehensive medical service for children charged with supervising the well child in addition to the child who was ill. In such a scheme the family doctor would be in charge of a unit comprising perhaps 1,000 children, with their mothers, and he would work in close relation to a hospital service providing out-patient consultations and in-patient beds.

In further discussion the part which the British Paediatric Association might take in the future planning of paediatrics was emphasized by Dr. K. D. **WILKINSON**, Dr. A. G. **OGILVIE**, and Dr. **DONALD PATERSON**. Dr. **RICHARD ELLIS** raised the question of regional planning in paediatrics and the need for the establishment of consulting centres visited by physicians on the staff of a university paediatric unit. He felt also that the experience of paediatricians of all nationalities would be required in combating the effect of widespread famine conditions in occupied Europe. Dr. L. G. **PARSONS** (President) urged closer co-operation between hospitals and welfare centres, and also the greater stressing of paediatrics in the final examination of students.

A resolution was passed instructing the committee to interest themselves in, and advise any appropriate authority on, current paediatric problems, and for this purpose it was empowered to co-opt members both from the Association and from other bodies.

Correspondence

Special Clinics and Planning

SIR,—The figures you publish for the rising death rate of pernicious anaemia make sad reading (Aug. 8, p. 176). A similar rise is occurring in the death rate of diabetes mellitus (Peck, F. B., 1941, *Southern Med. and Surg.*, **103**, No. 10). Yet we know that in efficient hands, such as those of Joslin and Wilkinson, the mortality from these diseases can be greatly reduced. It has now been my experience to found anaemia clinics at two teaching hospitals in succession. At each hospital a large proportion of the patients with pernicious anaemia who had been treated as in-patients were in bad shape when they were followed up. They subsequently responded to treatment and remained well while attending the anaemia clinic. Undoubtedly the patients were to blame for neglecting treatment when they felt themselves cured. Nevertheless it is clear that private practice has not provided a satisfactory solution for the care of patients with diabetes mellitus or pernicious anaemia, who require lifelong maintenance treatment under laboratory control. It is unlikely that local health centres dealing with populations of the order of 25,000 will achieve much better results.

Special clinics for this type of illness must be confined to a relatively small number of key hospitals in each area. Moreover, their setting-up must be carefully controlled, for there is a real danger that clinics for individual diseases may multiply too fast and do harm in the end to the general practice and teaching of medicine. There is an obvious distinction between diseases like peptic ulcer and asthma, in which the patient takes no harm if he neglects treatment when he feels well, and pernicious anaemia and diabetes mellitus, where such neglect may prove fatal. Finally, methods must be devised for keeping in touch with the practitioner, so that he does not feel robbed of his interesting cases and is in a position to deal with the dangerous emergencies which may arise when a patient with pernicious anaemia or diabetes mellitus contracts another illness. This is an important section of medical planning which as yet has hardly received the consideration it deserves.—I am, etc.,

Oxford L. J. WITTS.

Medical Planning and Research

SIR,—There appears to be one aspect of future planning in the interim report of the B.M.A. Planning Commission which has not received the attention I believe it deserves, even if one remembers that the report is pragmatic and deals primarily with the practice of medicine. I refer to the question of medical research, both clinically and in the laboratory. In my own field of endocrinology most of the fundamental advances in the understanding of disease and its alleviation or cure have depended upon experimental research, and I doubt if this is qualitatively less true of other fields of medicine. Most clinicians, during their practice of medicine, have felt with deep regret the inadequacy of the therapeutic resources available to them, and this has led in some instances to a keen and healthy interest in the social and preventive aspects of medicine, which branches of medicine are rightly assuming increasing importance. No one would doubt that medical research in this country is also developing on sound lines, but I feel that after the war its growth and depth can be vastly accelerated and augmented, and, further, that many of those practising medicine could participate in a very useful manner.

In the first case no one should be able to attain consulting status who has not made his contribution to the advance of medical knowledge. This would, in practice, mean that all medical registrars (at least in teaching hospitals) would be required to undertake research for a period of two years or more in the research department of their hospital. In my opinion no one is unsuited to participate in research, although the quality of the results is bound to vary enormously. Nevertheless, anyone working in a proper research department is bound to make a contribution to medical knowledge, even though it may be of a negative character. We must also destroy the opposite delusion that a brilliant research worker is necessarily, or even probably, a bad clinician. It may well be, as some contend, that research work at its optimum is a full-time job carried out by those whose lives are entirely devoted to it, but this does not mean that valuable research cannot be carried out by others, or that we should throw away any opportunity of creating a research army working in conjunction with leaders in this field, as indicated above. Such research work carried out over a period of years would enable those who ultimately restrict their activities to clinical work to appreciate the qualities of their research colleagues and to interpret their work. It might also help some research workers to appreciate the potential quality of collaboration with their clinical colleagues.

Research in medicine, however, is by no means limited to the laboratory, and there are wide opportunities in the clinical and pathological fields. Such work is being undertaken every day by clinicians in hospitals in collaboration with their colleagues in the pathological departments. I think, however, that it is gradually being realized that the properly trained medical practitioner can also make valuable contributions in the clinical side of this field providing that his collaboration is welcomed, stimulated, and even sometimes directed, and also providing that he is given the necessary time and facilities. I believe that any post-war scheme for medical reconstruction should bear these facilities in mind and make them practicable from an economic aspect. Is it not realistic to believe that this approach will bring to light more than one James Mackenzie or Frederick Banting?

If the above considerations bear fruit, and if an economic disparity between research work and medical practice is adjusted equitably, I think that the whole field of medical practice will be enriched by the creation of a research atmosphere and activity that is bound to yield valuable results in our fight against disease.—I am, etc.,

London, W.1. S. L. SIMPSON, M.D., F.R.C.P.

Social Medicine and State Medical Service

SIR,—Having had a long experience of public health work as well as general medical practice I venture to submit a few suggestions on this subject. Medical reform has been "hanging fire" too long, and even when there has been reform there has been obstruction to progress. The National Health Insurance Act, for instance, included a scheme for local committees to speed up preventive measures; this was never put into operation. Insurance Committees also had power to press public health authorities to speed measures to improve health, but they were never used as they should. Later, when the Ministry of Health Act was passed, it was expected there would be unification of medical services; this also has not been achieved, as shown, for example, by the industrial medical service being under one department and the school medical service under another, while the N.H.I. service is distinct from the local public health service. I remember attending a large meeting in Bristol in 1920, after the passing of the Ministry of Health Act, at which Lord Dawson of Penn and Sir Dawson Williams, Editor of the *B.M.J.*, were present; all were enthusiastic at the prospects of great things being done, yet all of us know what happened after.

Now we are busy again. In 1938 I gave a presidential address to the Derbyshire Branch of the B.M.A. on "Medicine and the Public Health," in which I suggested that the N.H.I. service should be joined locally with the public health service under a medical officer of health, who would be of a new type—more of a physiologist and consulting physician with a bent for research than an administrator. He would have at his disposal records of the different general diseases (as well as infectious diseases) that the local population suffered from through the N.H.I. part of his work; and similar information on the illnesses caused by or related to work in factories, including disability, through the industrial section of his organization. In that paper I gave much detailed information obtained from sources not usually open to a M.O.H., and the picture was an astounding one.

What I desire to stress is this: (1) Medicine must be integrated as one organized body under the State, including in its scope general practice, the health services, industrial medicine, the school medical service, and maternity and child welfare work; and these services should be linked with the large hospitals and universities and research centres. An active intelligence bureau should be available to it. (2) There must be a different approach to medical reform; delay like that from 1920 to 1942 in getting things done is inexcusable, and we medical men are to some extent to blame.

Medical reforms are, unfortunately, as to their actual embodiment in law, largely in the hands of lay persons unacquainted with details and ignorant of what is vital and what is not. For this reason, therefore, we medical men must not hold ourselves aloof from medical politics: rather must we, flushed with humanitarian feeling, push forward for what is needed, even with violence (in the moral sense) if necessary; provided, of course, what we advise is in keeping with modern medical knowledge and with a sane philosophical outlook.—I am, etc.,

Glossop E. H. M. MILLIGAN.

A Physician Free from Bondage

SIR,—In these days, when the art of medicine is in danger of losing its individualism by submergence into the civil service, it is refreshing to look back at such people as Sir Wilfred Grenfell. Just fifty years ago a young doctor who had worked under Sir Frederick Treves landed from a sailing ship on the barren forbidding coast of Labrador. He had abandoned that security which coaxes so many of us from our more ambitious aims, and exchanged a promising career in London for the life of a pioneer.

Grenfell crossed the Atlantic in characteristic fashion, sailing his own ship, which was no larger than the famous *Matthew*, and following almost exactly the course taken by John Cabot just four hundred years before. He found no medical or social work. At the first port of call he was led to a tiny turf-covered hovel in which lay the bread-winner of the house dying of pulmonary tuberculosis and surrounded by a forlorn family of six half-starved children. During the first eight weeks of that voyage he saw over nine hundred Anglo-Saxon and Esquimaux patients. Unlimited opportunities presented and Grenfell accepted the challenge. Like his ancestor, Sir Richard Grenville of the *Revenge*, he was prepared to take on any odds.

He built hospitals and nursing stations, schools and industrial centres. When it became customary for the people to leave their orphaned children to the doctor, he founded orphanages. Finding deficiency diseases common, he encouraged the cultivation of vegetable gardens and made greenhouses to foster the young plants. Ice and uncharted reefs take their toll of fishing schooners to this day, but many vessels have been saved by the dry dock that Grenfell constructed. Some of his ventures, such as the introduction of reindeer, failed, and his endeavour to improve the economic lot of the people sometimes stirred jealous opposition, but he had no personal ambition and feared no one. Each season saw him on his travels. In summer he navigated the hospital ship *Strathcona* into every harbour of the six-hundred-mile coast. In winter he visited patients by dog-sledge, driving his own team of eight husky dogs. These dogs he had trained himself, and they were able to haul an 800-lb. load all day, averaging 8 to 10 miles an hour.

Sir Wilfred Grenfell was a visionary who had the courage to follow his dreams and turn them into reality. He was concerned only with the welfare of the people he served. On their behalf he fought against ignorance and red tape and won a greater victory than he knew. On Oct. 9, 1940, Sir Wilfred Grenfell died. But his inspiration lives on in the work that he created.—I am, etc.,

C. Denley Clark.

"Orthopaedic" or "Orthomorphic"

Sir,—I am in complete agreement with the statement made by Brigadier Max Page (July 18, p. 79) on the misuse of the term "orthopaedic," but I venture to disagree with his assertion that the term used as an adjective was introduced into France in 1828 by Delpech. Actually the term was already in use in France at the beginning of the 18th century, and its first official introduction into medical terminology was by André in 1741 (*André, L'orthopédie ou l'art de prevenir et de corriger, dans les enfans les difformités du corps,* Paris, 1741, 2 vols.). As we can see, originally there was no misuse, and André carefully defined the limits. This term was again used by Levacher in the *Mémoires de l'Académie Royale de Médecine* in 1768.

Brigadier Page also affirms that the term "orthopaedic" had a much wider application already in the latter half of the 19th century; in fact it was a great deal earlier. Discussion on the alleged misuse of this term started in France at the beginning of the 19th century with the same etymological objections now raised by Brigadier Page. Delpech, whom Brigadier Page claims to have been the originator of this term, was in reality its greatest opponent, his reason being that at that time the term "orthopaedic" was totally inadequate to express its wider use. He wrote: "*De l'orthomorphie par rapport à l'espèce humain ou recherches anatomo pathol. sur les causes, les moyens de prevenir, ceux de guérir les principales difformités,*" etc. (Delpech, Paris, 1828, 2 vols.). This plainly shows his opinion of the term used. Another expression—namely, "orthosomatic"—was introduced by Bouvier (*Dict. de Méd. et Chir.,* Paris, 1834, t. 12, p. 293). But it was Delpech's term which was adopted by the contemporary medical dictionaries. Under "orthomorphie" they understood: l'ensemble des connaissances, qui ont pour but de prevenir et de corriger à tout âge les déviations," etc. (*Dict. des Dict. de Méd.,* Paris, 1850, t. 6, p. 110). For my part I consider the term "orthomorphic" ideal from an etymological and practical point of view, and would like to see it introduced into medical terminology.—I am, etc.,

French Hospital, London, W C.2 S. Galewski, M.D.

Use of the Term "Orthopaedic"

Sir,—In your issue of Aug. 1 (p. 142) Mr. H. Jackson Burrows asks me to explain why I have changed views expressed in 1935 and which he thinks worth quoting. In so far as the tone of my letter (July 18, p. 79) may be deemed at variance with those views, I should say that any change in my opinion has resulted from recent observations in the surgical organization of the Army Medical Service. We may tolerate slovenly and unscientific nomenclature in peacetime and yet find its use an encumbrance under war conditions.

In my letter to you I instanced two examples of undesirable repercussions from the present application of the term "orthopaedic": the remedy to such confusions may not be as simple as I suggested—but I think it should be sought.—I am, etc.,

C. Max Page.

Sir,—Brigadier Max Page has raised an important point in his letter of July 18. The regulations of the E.M.S. enumerate a certain and considerable group of injuries which must be treated at orthopaedic centres and hospitals. The men staffing these centres are termed "orthopaedic surgeons." Some have had a wide training and experience in traumatic surgery and are very competent to treat patients with multiple injuries; others appear to have practised orthopaedics in the sense of the treatment of deformity and surgical tuberculosis, and some of these seem not to have the experience necessary to take charge of patients suffering from acute and multiple injuries. Disputes on definitions are unsatisfactory. When, however, the regulations of a service such as the E.M.S. lay down that certain injuries must be treated at orthopaedic centres, it is desirable to know what is meant by the term "orthopaedic surgeon."

Since trauma is not confined to the bones, the staff of a traumatic unit needs a wide training as well as knowledge of the treatment of fractures. I suggest, therefore, that a general training would be of rather more value in qualifying a man to be a surgeon in a so-called "orthopaedic centre" of the E.M.S. than previous experience in "19th century orthopaedics."—I am, etc.,

London, S E 1. T. W. Mimpriss.

Sir,—I suggest the following to replace the above term: "orthodemic" or "orthochōldemic" (ὀρθόω, χωλός, δέμας, make straight, maimed, living body). The full term may be too fussy, so "orthodemic" is perhaps preferable.—I am, etc.,

Glossop E. H. M. Milligan, M.D.

*** This correspondence is now closed.—Ed., *B.M.J.*

Animals and Plague

Sir,—The interesting note by Sir William MacArthur (July 25, p. 106) on the historical association of rats and plague, raises the question whether our forefathers had any idea of the rats' part in spreading infection. I am inclined to think that towards the end of the period when plague was common in Western Europe some such suspicion must have arisen. Arnaud Baric (quoted by Grimbert, *J. méd. Paris,* 1903, **15**), writing in 1646 on precautions to be taken against plague, says: "Si l'on pouvait faire mourir tous les rats ce ne servit que bon." More definite evidence, perhaps, is the fact that in 1647 the town council of Aberdeen, who seem to have had rather a flair for epidemiology, included in their anti-plague measures "poysone laid for destroying myce and rattons."

Gilbert Skene's reference to moles was presumably derived from Avicenna. Why he added "the serpent" is difficult to say. He practised in Aberdeen and Edinburgh, and probably had little opportunity for studying the habits of serpents. But statements regarding the appearance of reptiles, especially frogs and toads, when plague was imminent are common among early writers.

The pig was regarded with suspicion. He was supposed to be susceptible to the disease, and his flesh, according to Rhazes, was a specially unsuitable diet for the plague-stricken. Boccaccio says that he saw two swine rooting among the rags of a man who had just died of plague, and that in less than an hour both were dead. Another pig, equally ill advised, was guilty of the same indiscretion at Mendenblick in Holland, and served to point a moral in various plague tractates. Even though in good health the pig, owing to his neglect of personal hygiene, was considered a danger to the community. Sennertius emphasizes that in time of plague it is essential that the streets be cleared of droppings of swine and geese, because their smell aids the spread of infection.

Dogs and cats appear to have been regarded as carriers rather than as themselves liable to contract plague. Victor de Bonagentibus refers to the risk of their sleeping on infected material. Ambroise Paré thought they might carry infection by eating the remains of food left by patients, but that they rarely acquired the disease themselves—"pource que leur temperament n'y est pas disposé." On the other hand Mercurialis believed that domestic animals might become infected and transmit the plague to persons or fomites. Municipal authorities probably paid little attention to those epidemiological speculations, but killed off stray dogs and cats on the chance of their being dangerous. The goat, however, was the friend of man. His natural odour was supposed to counteract the plague venom in the air: "C'est qu'une mauvaise odeur chasse l'autre," Paré explains. Mercurialis, dining with the Chancellor of Hungary, was surprised to see a large goat in the room and was informed that it was kept there as a prophylactic! The spider also played her humble part. Her web was supposed to have a special power of absorbing the plague venom, and domestics were sometimes forbidden to remove cobwebs from rooms when the disease was prevalent. Diemerbroeck regarded this as folly, pointing out that if cobwebs did absorb the infection of plague they must be most dangerous things to have about a house and should be removed and burned as soon as possible.

Those old notions are something more than ancestral absurdities, fit only to amuse a better-informed age. They were founded, often quite logically, on the orthodox doctrines of the times, and are not without importance to those who are interested in the evolution of epidemiological theory.—I am, etc.,

Dumfries JOHN RITCHIE.

Rehabilitation

SIR,—The obvious and tremendous advantages of rehabilitation centres to the individual and to the man-power of the country, quite apart from the fact that the Ministry of Health has been urging the necessity for rehabilitation for the treatment of casualties in the Forces, make one read with interest every article written on this subject. Such interest is especially roused when an article appears written by so authoritative a person as Sir Robert Woods (July 25, p. 89), who so fully appreciates the importance of, but also the difficulties attendant on, rehabilitation centres.

One sympathizes greatly with his observations on the need for trained personnel and the impossibility almost of obtaining or retaining these important people. But when one reads the final paragraph of his article, one gasps at the tragic consequences of the, presumably, authoritative statement on the policy of the Ministry of Health:

> "The policy of the Ministry is, at any rate at present, *not* in favour of the setting up of rehabilitation 'centres.' *After* the war, however, it is almost certain that such institutions will be found necessary, and the present emergency might, if the individuals were available, lead to the equipment of a number of men and women with a training which would render them competent to supervise a form of therapy *whose post-war establishment will represent a great and long-advocated advance in the treatment of injury and disease.*" (The italics are not in the original.)

Is it not too pathetic an exposure of lack of foresight and of present endeavour to suggest, even, that a form of therapy which represents such a great advance in treatment shall not be available for the men and women who are fighting for us, whether at the front or in our bombed cities, or in munitions and other wartime efforts? Is not our man-power, as it is, so comparatively small that it is of paramount importance that every man and woman shall be restored to full health at the earliest moment possible? Have we not yet sufficiently learnt from past disasters that the attitude of "mañana" must be replaced by one of immediate and thorough preparedness? One can only hope that this statement of Sir Robert Woods does not truly represent the attitude of the Ministry of Health, and that this Ministry will do everything possible to encourage the establishment of rehabilitation centres.—I am, etc.,

Ruthin H. MORRISTON DAVIES.

Urethral Instrumentation

SIR,—I willingly accede to Lieut.-Col. Henry Smith's request (July 25, p. 111) for an account of the present-day teaching of how to pass a silver-plated catheter, but a practical demonstration by a surgeon experienced in urethral instrumentation is the best way to learn the correct technique. This is the most difficult of all types of catheters to pass successfully, but under certain conditions it may be the only one which will relieve the patient's distress.

After sterilization by boiling, lubricate the whole instrument with medicinal paraffin. The custom of dipping the tip only of a catheter in a lubricant is a bad one. Friction between instrument and mucous membrane must be reduced to a minimum. The penis should be held on the stretch at an angle of 40 degrees with the pubis. The tip of the silver catheter is inserted into the urethra, its shaft being held parallel with the abdominal wall. With the penis still on the stretch gently guide the instrument along the urethra until it reaches the fixed portion of the tube—that is, the bulbous urethra. Then raise the catheter slowly until the shaft is at right angles to the pubis, the penis at the same time being depressed towards the perineum. The tip of the instrument is now in contact with the sphincter urethrae. The final movement consists in a slight relaxation of the hold on the penis and pressing the catheter down until it comes to lie between the two thighs. During this part of the manipulation the curved portion of the instrument is sliding along the membranous and prostatic urethra into the bladder. Never allow the tip of the catheter to deviate from the middle line. If it does, a false passage results.

For each type of catheter—metal, rubber, or gum elastic—there is a special technique. As Col. Henry Smith wisely states, "The subject is a most important one." I am glad Dr. E. C. Atkinson in his excellent letter has referred to Mr. Ogier Ward's important contribution to this subject.—I am, etc.,

London, W 1 CLIFFORD MORSON.

Ileostomy for Ulcerative Colitis

SIR,—I read with much interest your report on ulcerative colitis (July 25, p. 107), but I cannot agree with the statement that the mortality is high in cases of ileostomy. I first performed this operation in 1917 for cases of chronic amoebic dysentery when I was a surgical specialist in Mesopotamia. The operation was reserved, as a last resort, for cases which failed to respond to medical treatment, and in the majority the patient improved to such an extent that he could be evacuated to the base.[1]

In my experience appendicostomy is useless for any form of colitis. It provides no rest to the bowel and merely permits of irrigation, and the caecum can easily be reached by rectal irrigation. Ileostomy provides maximum rest to the inflamed colon, and excoriation of the skin in the region of the ileostomy can be prevented by the application of a mildly acid ointment and the administration of ferri redactum 5 grains t.d.s. The liquid consistency of the discharge can be modified by the administration of chalk and opium powder.

For 25 years I have performed ileostomy for any form of ulcerative colitis when, as a last resort, patients have been referred to me by medical colleagues. I have no note or recollection of any fatality which could be attributed to the operation. In many cases improvement could only be described as dramatic, and I am convinced that this procedure deserves a much wider recognition as a life-saving measure.—I am, etc.,

London, W 1. MCNEILL LOVE.

"Silent" Sinusitis

SIR,—Miss Rosa Ford (Aug. 1, p. 128) raises problems of interest to rhinologist and ophthalmologist alike. Her theories are not without obscurity, but her evidence for them urges both comment and inquiry.

Is the evidence in both her cases that a sinusitis existed entirely convincing? In Case 1 three rhinologists found no clinical signs of it and radiographs showed none. When the third rhinologist opened the antrum "the disease was seen." It would seem important to know what disease. Was pus present in the antrum? If so, then would not radiographs have shown it? A week later, it is stated, there was a profuse flow of blood and mucus from the nostril. Must this have been due to disease of the antrum? May it not have come from the nose itself or have been due to the operation of antrostomy? In Case 2 there were no clinical signs of sinusitis. "Nasal medication resulted in considerable nasal discharge." Is this proof that sinusitis existed? It is not mentioned which sinus was believed to be affected. May not the nasal medication have caused the discharge without sinusitis being present at all?

But I am no rhinologist. Miss Ford mentions, as though in passing, contraction of the visual fields as if this were a mere symptom of nasal sinusitis. Any possible connexion between the two conditions would seem to require explanation, if not proof. It is relevant to ask what form of contraction was found, whether concentric peripheral contraction, or hemianopia, nasal, temporal, or homonymous, or a scotoma, central or paracentral. How does sinusitis produce this contraction? Miss Ford is silent. The mechanism is indeed obscure. The "hidden oedema" of which she writes is perhaps a clue, but the mystery remains.

---

[1] *Practitioner*, July, 1920

Miss Ford will, I hope, enlighten us, for without answers to these questions no conclusions can be certain or even safe. We must, I submit, suspend judgment as to whether in these cases the visual fields were indeed affected by sinusitis or whether sinusitis did in fact exist at all.—I am, etc.,

Lincoln. C. NEWLYN SMITH.

Headaches and "Silent" Sinusitis

SIR,—The two cases of "silent" sinusitis reported by Dr. Rosa Ford (Aug. 1, p. 128) are of peculiar interest to every general practitioner, as I am quite sure that we have all had similar experiences. I, personally, can quote many cases in which sinusitis has been ruled out by the consulting rhinologist, only to find when operation has been resorted to that gross sinusitis is present.

As Dr. Ford states, in many cases of sinusitis there is nothing abnormal to be seen in the nose or in the radiographs. Such negative radiological findings depend upon the fact that swellings of the sinus mucosa found in association with headaches are often "transradiant." We have long employed radiopaque substances as a contrast media in order to display changes in the soft parts elsewhere in the body; and if the sinuses of patients complaining of headache are examined radiologically after the introduction of lipiodol, it will often be found that the membranous lining—approximately of normal thickness in the interval period—may swell to a surprising degree during a headache. Such a contrast medium may be introduced without disturbance to the patient by the "displacement" or "replacement" method of Proetz,[1] and is of wider diagnostic application than in the search for contraction of the visual fields upon which Dr. Ford relied in the cases she quotes, and which is likely to be of service only in cases of posterior sinusitis. I have employed the replacement method for several years in general practice, and the findings support the idea put forward by Sluder[2] 30 years ago that migraine may be produced by sphenoidal trouble.

The negative clinical findings in the nose depend partly on the fact that streptococci may exist in the nasal mucous membrane, giving rise to the production of oedema rather than pus, and partly on the fact that headaches may be produced by swellings which are allergic rather than infective. In the latter type of migraine excellent results are obtained by employing the replacement method, using ephedrine combined with normal saline in order to prevent the allergic swelling of the mucous membrane.—I am, etc.,

Alderley Edge, Cheshire J. J. CRAIG.

Narco-analysis

SIR,—As the author of articles on narco-analysis (*Lancet*, 1936, **1,** 55; *J. ment. Sci.*, 1936, **82,** 416; *Med. Pr.*, 1937, **194,** 321) I have been interested to read Major J. F. Wilde's article (July 4, p. 4) followed by Dr. J. L. Clegg's criticisms (Aug. 1, p. 140). Wilde rightly emphasizes the difficulty experienced by many Service patients (and civilians too) in confessing to a strange consultant their personal and private problems. The great advantage of narco-analysis as compared with other psychotherapeutic procedures is that by overcoming this reluctance it saves time—a factor even more important in war than in peace. For this reason I disagree with Clegg's assertion that narco-analysis should be resorted to only when other methods have failed. Clegg's second point—"that it is not a reliable means of effecting a transference"—is true of all psychotherapy Admittedly the state of transference cannot be achieved in every patient. Nevertheless, by means of narco-analysis it is possible to achieve this in many patients whose previous state was either apathy, inaccessibility, or even negative transference. His third point—"that it is not a means of gaining access to deeply repressed material"—is contrary to my own experience in analysing more than 1,000 patients. Finally, he admits that in one of his cases the "correctness of the diagnosis was confirmed" only by means of pentothal—and yet he jibs at the method because the patient subsequently denied his previous confession. Surely such denials are well known to all psychotherapists whether they practice orthodox analysis, hypnotism, or merely the sympathetic talks advocated by Dr. Clegg.

It is to be hoped that real progress will be made in the Services towards perfecting the technique of narco-analysis.—I am, etc.

Dorchester. J. S. HORSLEY.

SIR,—The letters of Major J. F. Wilde (July 4, p. 4) and Dr. J. L. Clegg (Aug. 1, p. 140) are of considerable interest. I too have had more than a little experience both of hypno-analysis and narco-analysis (chiefly with pentothal sodium). The relative merits of these two methods must necessarily depend on personal factors. It is clear from his statements that Dr. Clegg's mastery of the technique of narco-analysis is not comparable to his skill as a hypnotist. With most of us it is the other way. But I do not suggest that the technique of narco-analysis is simple—certainly to get the best results the sterotyped method of Dr. Wilde is inadequate. The exact dosage and the rate of administration can of course be varied within wide ranges and the level of unconsciousness reached will vary accordingly. Dr. Clegg does not so much as mention the dosage he favours. It is perfectly true that much of the material collected under narco-analysis is not repressed material but merely withheld material. However, Dr. Clegg admits the main argument for narco-analysis—namely, that it is an effective short cut—and surely this is the aim of most modifications of analytical technique.

The two following examples are relevant to Dr. Clegg's contentions:

(1) An alcoholic patient in hospital had had eight sessions of narco-analysis. One day he threw his tea-tray across the ward and a book through a window-pane. This outbreak was entirely unexpected and unrelated to previous behaviour. When I asked him what had happened, he said, "Doctor, you must give me another dope—there's something there about my sister that we haven't got hold of yet." Next morning another session of narco-analysis produced a circumstantial account of a very perverted sexual incident with his sister when he was a small boy. The revelation relieved the patient's anxiety with very satisfactory results. In the circumstances I am not greatly interested in whether the incident was repressed or not. I know that cure was accelerated

(2) A young woman at her first visit asserted that her relations to her mother were excellent, adding that there was a very close bond between them. During the first session of narco-analysis she said, "I *hate* the woman—God! how drunk I must be to say that."

—I am, etc.,

London, W 1. H. CRICHTON-MILLER.

Declining Population

SIR,—Mr. Green-Armytage has presented his comments on "declining population" (Aug. 1, p. 143) in truly provocative fashion.

Just as those who do routine gynaecological O.P.'s are accustomed to finding "strawberry erosions" in the young bride and mother who has used contraceptive measures, so officers at welfare centres who prescribe such measures are likewise thoroughly accustomed to such findings on the first examination of the young bride, mother, and even virgin. In other words, such conditions are common, and if they were accentuated by the use of such contraceptive measures the vast number of records supervising the "condition of cervix" at birth control clinics would long since have revealed the important fact. Officers at these clinics—in common with any other gynaecological observers—have frequently the interest of seeing such lesions heal spontaneously, and alternatively of observing how often they do not delay a desired pregnancy by even a single month. Surely the serious cases of sterility are found among those women who, having failed early in their marriage to procure contraceptive advice, have rashly resorted to criminal abortion with its coincident evils.—I am, etc.,

London, N W. JOAN MALLESON.

Delayed Union of Fractures

SIR,—I was much interested to read in your report of the meeting of the British Orthopaedic Association (July 11, p. 50) that not only did "most of the speakers" hold that delay in the union of fractures was commoner than formerly, but that Mr. B. H. Burns had the insight to blame the use of unpadded plasters for this delay. Personally, I have of late years always used such splintage in the treatment of fractures of the leg, but I have done so with the definite knowledge that I was delaying union by some 4 or 5 weeks. Such a delay is amply counterbalanced (to use Mr. Burns's expression) by (1) the certainty of retention of a good reduction; (2) greater freedom for the patient; and (3) a tremendous reduction in the amount of supervision called for from the surgeon.

Any surgeon who has obtained full union, with working ability, in the short space of about 5 weeks in the case of a fracture of the shaft of the humerus by treating it with a wrist sling only, or occasionally with the addition of a weight slung to the elbow, knows full well that the fashionable theory that complete immobility is essential for the union of fractures is, at most, but very partially true. There is certainly equal truth in the older theory that movement promotes union, as so well evidenced in the rapid uniting of fractured ribs. In fact Blair (*Surg. Gynec. Obstet.*, 1938, 67) sums up experimental work on the union of fractures as follows: "Following fracture, immobilization and disuse cause atrophy of bones. Early activity is known to prevent this decalcification, and it apparently hastens the formation of callus and solid union."

The plaster case immobilization school are, perhaps, most insistent on such firm fixation in the case of fractures of the carpal scaphoid. In fact Watson-Jones in his textbook on *Fractures* says: "Every single movement of the wrist-joint puts back the process of repair by several days," and in the *Journal* of May 26, 1934, that "the one and only cause of non-union is failure of adequate immobilization." He recommends at least 6 weeks in plaster followed by 6 in strapping, making a minimum of 12 weeks in all before the patient is out of bondage. Now for the last 15 years I have been treating simple uncomplicated fractures of the carpal scaphoid by very incomplete immobilization in strapping—elastoplast since its advent. I take care to check my results by radiography and follow up, and so far have always obtained good radiographic union with freedom from all symptoms in from 5 to 6 weeks. I have also been fortunate enough to escape any cases of non-union, although I have seen a number of such treated by more orthodox means in plaster.

The method I use is to strap the wrist, base of the hand, and the thumb in 2 or 3 layers of elastoplast. This strapping should be so tight that the patient states that he "cannot move the wrist." A sling is provided, and the patient told not to use the hand. After 5 to 7 weeks, when all such symptoms as pain on movement, tenderness over the bone, etc., have passed off, a radiograph is taken. If this shows full union all treatment ceases. The patient is told to do only light work for a few weeks. The following 3 cases are typical.

1. L. S., aged 17½, errand boy. Seen day of accident. Radiograph shows transverse fracture of waist of scaphoid. Firm strapping applied. 38th day strapping removed. Union good. Patient told to report in one week. He did not do so but attended for follow up 6 months later. Then he stated that he resumed full work immediately after his last attendance at hospital, was now on munitions and waiting to be called up, and had no symptoms of any sort. The wrist showed no signs of injury.
2. R. P., aged 17, van guard. Seen day after accident. Fracture of waist of scaphoid shown radiographically. Put up in strapping. 39th day seen by my holiday locumtenent. No symptoms. Strapping removed and patient told to resume work in one week. Failed to attend for follow up as he had been called up.
3. R. B., aged 20, seaman. Seen day of accident. Fracture of scaphoid and of cuneiform shown in radiograph. Strapped on 2nd day. 46th day radiograph showed full bony union. No symptoms. Strapping removed and patient told to attend for exercises three times a week. 60th day patient attended. Had had no exercises as hand was "all right." Told he could do light duties, but stated that he was going to rejoin his ship as he felt he was cured. Did not attend for follow up as he was in the Navy.

The advantages of such a method of treatment, if successful, are obvious: shorter period of disability, no uncomfortable plaster case, and no massage or physiotherapy afterwards. I am convinced that many of those cases showing delayed union and requiring 3 or even 4 months in plaster owe that delayed union to the completeness of the immobilization.

Looking at fracture treatment as a whole, it is quite clear that as yet our knowledge of the factors underlying the union of fractures is far too incomplete for the formulation of any sound explanation covering all the known facts. Might I suggest that the advocates of complete immobilization in all fractures are victims of that outstanding vice of the medical fraternity through all the ages: the formation of theories on insufficient grounds and the basing of treatment dogmatically on such theories—in other words, of treating medicine (and surgery) as a science and not as an art.—I am, etc.,

Wimbledon, S.W.20. A. J. HOBSON.

Passive Movements for Joints in Paralysed Limbs

SIR,—I am in entire agreement with Prof. Seddon's views on the necessity of passive movements of joints in paralysed limbs. In this hospital there are always a number of cases of recent poliomyelitis, and I have always insisted on passive movements of all the joints in the paralysed limbs through the whole range of their movement each day by the masseuse. Stiffness of the joints in these cases through lack of this precaution is often troublesome, and I have seen more than 50% limitation of movement of the knees in both children and adults where treatment has been concentrated on splinting and massage but not on movement, both active and passive. The stiffness may occur in the first few weeks of the disease, and complete mobilization may take many months to obtain; in fact repeated manipulation under an anaesthetic may be necessary even in a completely flail limb. Surely a partially or completely flail limb is sufficient disability without adding the insult of limitation of movements of joints which, when wrenched, are painful, and the stiffness of which may even cause a fracture of one of the long bones.—I am, etc.,

Royal National Orthopaedic Hospital,
Stanmore. JOHN A. CHOLMELEY.

"Fibro-psychosis" of the Amputation Stump

SIR,—We are all acquainted with the tender amputation stump, especially of the finger. A small number of such cases are frank malingerers, a good many more suffer from a true causalgia, but in the great majority the condition is largely neurasthenic, and if the patient can be persuaded to resume work the complaint of tenderness and electrical shocks in the stump gradually disappears. In describing a case for a medical board, wherein pain and tenderness of this character was complained of in a crushed finger end, I dictated to my secretary that there was some fibrous ankylosis of the terminal joint. She misheard me and wrote "fibro-psychosis." The slip gives so complete a clinical picture of a severe case that I think it might well be adopted in the *Nomenclature of Diseases.*

Incidentally, I have been employing periarticular injections of procaine in the region of the brachial artery with some success in relieving the cases of true causalgia, 5 c.cm. 4 times a week for a fortnight.—I am, etc.,

Sunderland. W. GRANT WAUGH.

The Problem of Abdominal Pain

SIR,—My attention has been drawn to an article by Mr. Francis R. Brown (May 2, p. 543) in which he claims to have been the first to point out the importance of the relative embryological position of an organ in determining the localization of pain in the human being; but it will be clear from the following quotation that the same idea had, however, been submitted in a publication of mine in 1931 (*Ptosis of the Female Pelvic Viscera*, p. 43).

> "The Mullerian ducts are, developmentally, postero-lateral organs which subsequently acquire a midline relation; this probably explains the variations in the position of referred pain when they become affected by disease in the adult . . . ; so when disease develops in the Fallopian tubes, pain usually commences in the iliac region and does not spread to the midline until the peritoneum is involved. The reverse occurs in the appendix"—pain commences in the midline before it extends laterally—"and gall-bladder, which are, developmentally, organs originating in the midline of the foetus. . . . Again, the Fallopian tubes develop originally in the lumbar region in the foetus, and one is not surprised to find that in some cases of salpingitis the pain may be referred in the paracentral

> line of the body as high up as the lower subcostal region . . . ; the cervix occupies a midline position, but was originally postero-lateral; so when cases of chronic cervicitis complain of any pain other than a bearing-down pain, the pain is felt in the sacral or iliac regions rather than in the suprapubic region."

If one can assume that each viscus acquires the foundation of its nerve supply while still in its primary position in the foetus, it follows that the phenomenon of "referred pain" is explicable on anatomical grounds. While the relative position of the viscus is changing with the growth of the foetus, the viscus retains some proportion of its connexion with the central nervous system through the same intrinsic nerves that were laid down when it occupied its primary position, so the painful viscus is "felt" by the central nervous system to be still occupying its primary position, and any pain referable to the viscus is located in its primary position; but the clinician finds that this in fact corresponds with the site of referred pain, no longed occupied by the viscus (cf. the "phantom limb" felt after amputation). A pain which is so severe as to overflow into neighbouring areas is a radiating pain and should not be confused with a referred pain.—I am, etc.,

London, W.1. E. HESKETH ROBERTS.

Respirator Dermatitis

SIR,—Petro's account (May 23, p. 631) of respirator dermatitis corresponds with the clinical appearances observed in 9 cases among soldiers in hospital.

Patch tests on the forearm, in confirmation of the diagnosis, may be called for where the dermatitis is slight, or has already faded by the time the patient is admitted to hospital, or where the condition is obscured by a secondary impetigo which may involve other areas of the face and scalp. It was found that some of these men were very sensitive to the rubber of the respirator. Consequently, if patch tests are to be performed the precaution of using only small pieces of rubber should be observed. A blister reaction may follow, and if a large surface of rubber is applied the reaction may be severe and take some three weeks to subside.

Positive patch-test results are usually observed at the end of 36 hours, but in one case appeared only after 4 days, and in another a test which appeared to be doubtful had become definitely positive at the end of 4 days. It would therefore be desirable to keep the area tested under observation for a week. Late developing patch-test results have been described with other chemical antigens. It was found that a swab moistened with saline and rubbed over the inside of the rubber of the respirator, applied to the forearm, gave a positive patch test in these cases of respirator dermatitis. Hence the irritant "accelerator" or "improver," the composition of which is known, is saline-soluble and probably sweat-soluble. Thorough washing of the inside of the respirator with soap and water, to remove the dried sweat with the dissolved antigens, might have avoided a dermatitis in the less susceptible individuals. If possible, the piece of rubber, or the saline swab which has been rubbed over the inside of the rubber of the respirator, should be kept in place by bandaging rather than strapping, as the latter may itself give rise to a reaction and thus obscure readings.

One man who developed a respirator dermatitis has since noticed redness and itching whenever he wears his new respirator, which does not contain the offending chemical known to the authorities. He gave a positive reaction only after two applications of the rubber of the new respirator, separated by an interval of a week and applied to the same area of skin. There are, of course, many potential irritants among the chemicals used in the preparation of rubber, and Cox (*India Rubber Journal*, 1936, **92**, 724) has stated that rubber and latex can break down under the action of sweat to produce a resinous substance which is a potential irritant.—I am, etc.,

London, W.1. L. FORMAN, M.D., F.R.C.P.

"Positive Health"

SIR,—May I suggest this simple explanation as the basis of the definition: Positive health means health through effort—effort on the part of the patient, effort on the part of the medical attendant, and effort on the part of the local and national health organizations.—I am, etc.,

M. B. DOUGLAS.

Tetanus after Sulphonamide Treatment of Cavities

SIR,—Mr. J. C. Cherry (Aug. 1, p. 142) describes an interesting method of sterilizing a sulphonamide. I should like to suggest, however, that a "negative pressure" of 16 lb. to the sq. in. can only be obtained when the barometer is in the region of 32.5 inches, even with a theoretically perfect vacuum. This will reduce the practical value of the method very considerably in England whatever may be the case in the Free State.—I am, etc.,

Shipley. H. S. RUSSELL.

Obituary

News has reached this country of the death at his home at Birtley, Elizabeth Bay, of Dr. RALPH WORRALL, for many years a leading gynaecologist in Sydney. He was born in Ireland in 1859 and was educated at the Church of England Diocesan School, Waterford, and Queen's University, Belfast; he took the M.D. degree of the old Royal University of Ireland in 1878 and the M.Ch. two years later, after serving as resident at the Royal Infirmary, Belfast. In the early 'eighties he was in turn medical superintendent of the Mill Road Hospital, Liverpool, and honorary assistant physician to the Stanley Hospital, Liverpool. He then sailed for Australia and made his home in Sydney, and in 1886 began his long career as gynaecologist to the Sydney Hospital. In 1914 he was appointed surgeon to the Coast Hospital at Sydney. Dr. Worrall had been a member of the British Medical Association for 60 years and represented his Division at the Annual Meeting of 1907 at Exeter. In 1933 he published a paper in the *British Medical Journal* on total hysterectomy for non-malignant conditions, describing the technique of a method first performed by him in 1914 and for the 532nd time in 1932. He was a Founder Fellow of the Royal Australasian College of Surgeons, and an Honorary Fellow of the American College of Surgeons.

Dr. R. L. Worrall writes: My father, the late Dr. Ralph Worrall, whom I assisted at many operations, was distinguished by his medical judgment and human sympathy as well as by his technical skill. Among his contributions to gynaecology was his method of total hysterectomy, whereby removal of the cervix still left intact the central attachments of the pubo-cervical and sacro-cervical ligaments, these helping to preserve the structure of the vaginal vault after the operation. Towards the end of his career my father was invited by the Mayo brothers to visit their clinic at Rochester, and while in the United States on this visit he was elected an Honorary Fellow of the American College of Surgeons. He spoke in the highest terms of the American surgery which he saw, and was much impressed by the comprehensive efficiency of the Mayo Clinic. My father was a man of many interests, and did not let specialization narrow his field of medical and cultural vision. To the end of his active life he combined theoretical study with practice, taking a keen interest in all the major advances of medicine. I am much indebted to him for many things.

The Services

NAVAL AWARDS

The George Medal has been awarded posthumously to Surg. Lieut.-Cmdr. R. M. Bremner, R.N., for great bravery and devotion to duty in saving life.

The King has granted unrestricted permission to Surg. Lieut.-Cmdr. J. C. Moor, R.N.V.R., to wear the War Cross (Third Class) conferred upon him by King George of the Hellenes for services to the Allied cause.

The Royal Naval Volunteer Reserve Officer's Decoration has been awarded to Acting Surg. Cmdr. A. H. Shelswell, R.N.V.R.

ARMY AWARDS

The King has granted unrestricted permission to Lieut.-Col. (Acting Col.) A. J. Beveridge, O.B.E., M.C., and Capt. W. M. Burgess, R.A.M.C., to wear the Norwegian Military Cross conferred upon them by King Haakon of Norway in recognition of services in the cause of the Allies.

CASUALTIES IN THE MEDICAL SERVICES

Lieut.-Col. AILWYN HERBERT CLARKE, M.C., R.A.M.C., died from heart failure on June 23 in a prisoners of war hospital in Italy. He was born on March 4, 1893, the youngest son of the

Rev. H. S. Clarke of Weybridge, and received his professional education at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1916. He served in France in the war of 1914-18, gaining the M.C., and in 1921 took a permanent commission in he R.A.M.C. Between 1923 and 1927 he saw service in Egypt, n the Sudan, and at Shanghai, in 1928 he served with the British Army of the Rhine; and in the following year he was posted to India, in the Punjab, where he remained until 1935. After a brief spell in England he went to Egypt in October, 1935, and remained there until the end of 1936, when he returned to England. On the outbreak of the present war he first served for a few weeks on a hospital ship and then was stationed at a Scottish general hospital until June, 1940, when he was posted to Egypt, being taken prisoner a few months later. He leaves a widow. He had been a member of the B.M.A. since 1924.

Capt. **MARTIN DUNSMORE WINNING**, R.A.M.C., was killed on active service in Burma in March. He was born on March 12, 1912, and was educated at the University of Glasgow, where he graduated M.B., Ch.B. in 1938. He entered the R.A.M.C. as temp. lieut. in February, 1940, and was promoted capt. a year later. His home was at Kilmarnock. He was a member of the B.M.A.

Surg. Lieut. **JAMES YOUNGER WOODHOUSE**, R.N., who died suddenly on July 21, was educated at the University of Durham, where he graduated M.B., B.S. in 1925. After holding appointments at the Royal Victoria Infirmary, Newcastle-upon-Tyne, at Sunderland Royal Infirmary, and at Wallsend, he entered the Royal Navy as surg. lieut. in 1929, but relinquished his commission in 1933 and entered into partnership at Malton, Yorkshire. He re-entered the Royal Navy in July, 1939. He leaves a widow and one son.

Surg. Lieut. **WILLIAM PHILLIPS**, R.N.V.R., who was previously reported missing and who is now presumed to have been killed, was born on April 3, 1912, the third son of Mrs. Phillips of Burnham Market. He qualified M.R.C.S., L.R.C.P. in 1938 and had held the post of house-surgeon at West Norfolk and King's Lynn General Hospital. He entered the R.N.V.R. as prob. temp. surg. lieut. in May, 1940. He was a member of the B.M.A.

Prisoner of War.—Major I. A. B. Cathie, R.A.M.C.

Missing.—Temp. Surg. Lieut. A. P. Curtin, R.N.V.R.

DEATHS IN THE SERVICES

Lieut.-Col. **CLEMENT MALLINS**, I.M.S. (ret.), died at Worthing on July 29, aged 87. He was born on May 15, 1855, and was educated at Trinity College, Dublin, where he graduated M.A., M.B., M.Ch. in 1877, proceeding M.D. in 1888. He also took the M.R.C.P.I. in 1881 and the D.P.H. of the London Colleges in 1891. Entering the I.M.S. as surg. in 1879, he became lieut.-col. after twenty years' service, and retired in 1899. His Indian service was spent mostly at Hyderabad. He took part in the Tirah campaign on the North-West Frontier in 1897-8, gaining the Frontier medal with a clasp. He rejoined for service in the war 1914-18, serving in England for two years on a medical board at the War Office. He was a brother of the late Surg. Henry Mallins of the Bengal Service.

Medical Notes in Parliament

Diabetes in Death Classifications

On July 28 Mr. **LEACH** asked the Minister of Health whether there had been any change in the nomenclature of deaths in respect of certificates attributing death to diabetes and one or more other diseases. Mr. **BROWN** replied: In years before 1940 the statistical classification of deaths in respect of certificates attributing the cause to diabetes in conjunction with one or more other diseases was decided by means of rules giving the precedence of one disease over another as laid down in the Registrar-General's *Manuals of the International List.* These rules gave a high precedence to diabetes over other diseases. From 1940 classification in such cases has been carried out in accordance with the order of statement of the various causes on the certificate by the certifying medical practitioner, with certain exceptions laid down in the *Manual* issued in 1940. Since diabetes is frequently certified as merely a contributory cause of death, in association with another disease considered by the certifier as more important, the effect has been to reduce the number of deaths classified to diabetes in the statistics of cause of death, and the corrective factor to be applied to numbers of deaths in years before 1940 is 0.69. In the recent quarterly returns of the Registrar-General, the necessary correction had been applied to the diabetes deaths there shown for 1938 and 1939.

X-ray Examination of Recruits

On July 28 Mr. **HEWLETT** asked the Secretary of State for War what would be the estimated cost of x-ray examination of recruits on enlistment so as to avoid subsequent controversy over borderline cases. Sir **JAMES GRIGG** said that in view of the many uncertain factors he could give no reliable estimate of the cost. The difficulty of introducing any such scheme would be primarily in the shortage of the necessary apparatus and personnel.

Mortality from Pneumonia

On July 28, Mr. **ERNEST BROWN** told Mr. Leach that the number of deaths from pneumonia (all forms) registered in England and Wales from 1931 to 1941 were: 1931, 34,914; 1932, 30,743; 1933, 31,259; 1934, 29,751; 1935, 27,843; 1936, 28,890; 1937, 30,331; 1938, 27,467; 1939, 23,403; 1940, 29,195; and 1941, 26,418. The figures for 1931-9 were corrected to agree with the 1940 classification of deaths, and differed from those published in the Registrar-General's *Statistical Review* Part I, Table 6.

Proposed Transfer of V.A.D.s to A.T.S.

On July 28 Sir **JAMES GRIGG**, replying to Major Milner and Squadron Leader Fleming, said he received last week a deputation representing the British Red Cross Society and the Order of St. John of Jerusalem on the question of the proposed transfer of V.A.D. nurses to the A.T.S. As a result he proposed to invite these organizations to appoint representatives to a committee to be set up under an independent chairman to consider the relationship of mobile V.A.D.s to the Army. No final decision had yet been taken on the proposed transfer, and would not be taken until the committee had reported.

National Milk Scheme Grows

During a debate on agriculture and food, in the House of Commons on July 28, Mr. **MABANE** stated that the national milk scheme had progressed very well indeed; the percentage of the possible beneficiaries—expectant mothers and children—taking advantage of the scheme had risen from 70 to 87%. There were now 3,022,000 persons taking advantage of the scheme.

Glasgow Small-pox Cases

On August 4 Mr. **GROVES** asked the Secretary of State for Scotland if he was aware that a delay of 17 days occurred before Glasgow doctors were informed of the existence of dangerous and infective cases of small-pox; and why, although local general practitioners advised the local authorities of the seriousness of the position, no action was taken. Mr. **JOHNSTON** said that on June 14 the medical officer of health of Glasgow sent a letter to medical practitioners informing them that 6 members of the crew of a ship which arrived in the Clyde on May 29 had since contracted small-pox, that contacts were under surveillance, and that practitioners should inform him if any suspicious case came to their notice. All possible action to prevent the disease from spreading had been taken immediately the ship arrived, including the vaccination of the crew and passengers, and up to the date of that letter there were no cases in the city and therefore no need for a general vaccination campaign. The first case in the city itself appeared on June 25, and the decision to initiate a general vaccination campaign was reached on June 28. All needful publicity measures were taken immediately, and vaccination centres throughout the city were opened and began work on July 1.

On the same day Mr. **JOHNSTON**, replying to Mr. A. Edwards, said that the number of cases diagnosed as small-pox in Glasgow since the arrival of the ship was 40. Of this number, 9, including the original case, were members of the crew and 1 was a passenger. All the crew and passengers were vaccinated on May 29. Information as to the revaccination of passengers after May 29 was not available, but some members of the crew who remained in Glasgow were revaccinated on June 11. The original case was not recognized as small-pox until the patient was admitted to hospital in Glasgow, at which time the ship had not yet docked. The Port Health Authority, which was also the public health authority of Glasgow, was aware of the diagnosis before the ship docked at Glasgow. The medical officer of health was advised immediately the case was recognized as small-pox.

Venereal Disease in Forces

On Aug. 4 Sir **JAMES GRIGG** informed Mr. George Griffiths that special attention was being given to the spread of venereal disease among the troops; the necessary lectures were being given regularly, and precautionary facilities were available in all camps and barracks. The propaganda activities of the British Social Hygiene Council had recently been taken over by the Central Council for Health Education, and he would discuss with the Minister of Health the issue to each member of the Forces of their literature on this question. The incidence of venereal disease in the A.T.S. was very low indeed.

Medical Services in West Indies

During a debate on Colonial affairs in the House of Commons on August 4 Dr. Morgan said the medical services of the West Indies were disgraceful. Wonderful work was being done by medical men—general practitioners of exceptional calibre in the port medical work—by which they were keeping infective diseases away from these colonies. But when it came to internal conditions over which the medical men had no control, preventive work was being kept at a minimum, and they were concerned merely with ameliorative treatment for the relief of symptoms. The medical men were helpless in that they could not drain swamps to prevent malaria, dig latrines to prevent hookworm disease, or produce reservoirs for a good water supply. These conditions resulted from the Colonial medical policy of the Government. In the Colony of Trinidad, with a population of nearly 500,000, tuberculosis was rampant, as it was in Jamaica, yet there was no tuberculosis sanatorium. He understood that in Trinidad money had been subscribed privately to a considerable amount for a tuberculosis sanatorium, and they were simply waiting for a Government subvention to build the sanatorium.

Mr. Macmillan said it was not a question of voting money for a sanatorium but of finding a ship to take the materials over. As the position improved the Government would press forward with greater energy because of the disappointment of having all their plans and schemes held up by the harsh necessities of war.

Incidence of Pneumonia

Replying on August 6 to Mr. Messer, Mr. Brown said that although one drug in particular used in chemotherapy had lowered the fatality rate in controlled series of cases and proved its value in certain kinds of pneumococcal infection, the complications of pneumonia were such that it would not be justifiable as yet to look for any substantial effect on mortality from the disease in all its forms. Mr. Brown furnished Mr. Messer with the following table:

	Cases of Acute Primary and Influenzal Pneumonia Notified	Deaths from Pneumonia (all Forms)	Deaths from Influenza with Pneumonic Complications
1932	57,401	30,743	5,716
1933	65,009	31,259	10,744
1934	51,483	29,751	2,505
1935	46,901	27,843	3,325
1936	46,167	28 890	2,830
1937	55,896	30,331	8,910
1938	45,160	27,467	2,179
1939*	42,312	23,403	3,588
1940*	47,875	29,195	4,852
1941*	50,942	26,418	2,880

* Including non-civilians.

Further asked the relation between the number of cases of acute primary and influenzal pneumonia notified and the actual incidence of these conditions, Mr. Brown said that as there was no other reliable evidence of the incidence of pneumonia than that afforded by statutory notification he could not give the desired information. He did not believe there was substantial failure to notify pneumonia. Medical opinion was that there was over—rather than under—notification, and that conditions that could not strictly be described as pneumonia were so described.

London Medical Schools: Admission of Women

In answer to Prof. A. V. Hill on August 6 Mr. Bevin said he knew some medical schools in London did not accept women students. Whether such schools should accept them was a question for consideration by the Committee on Medical Schools. Prof. Hill suggested that the Minister should refuse to reserve any more men to begin the study of medicine in these schools unless the schools agreed to take in a proportion of women. Mr. Bevin said he must take all relevant facts into sideration before he agreed to reservations. No one regretted more than he the rigidity of the medical trade union rules.

High-frequency Apparatus

Sir Francis Fremantle inquired on August 6 what steps had been taken to enable medical practitioners to obtain release of their apparatus and resume treatment by ultra-violet and deep-ray therapy, as urged by a deputation from the Parliamentary Medical Committee and the British Medical Association. Mr. Grimston announced in reply that under a Home Office Order issued in the previous week these medical practitioners were now free to apply to the Post Office for a permit to use the apparatus in question. Permits would normally be granted subject to the provision of screening to an approved specification in order to avoid electrical interference with essential communications. A Press Notice (see *Supplement*, August 15) issued by the Home Office gave full information.

Medical Examination for Naval Flying Duties

In reply to Admiral Sir Murray Sueter on August 5 Mr. Alexander said there was no difference between the method and severity of the medical examination for entry for Naval flying duties and that for flying duties with the R.A.F. Before appointment to Medical Boards all medical officers underwent a special course of instruction in the medical examination for fitness for flying. There was close liaison between the medical departments of the R.A.F., and R.N. regarding the medical standards and methods of examination of candidates. Medical Boards received instructions as necessary. In cases of doubt regarding the medical fitness of a candidate for Naval flying duties, the case was referred to a civil or Service specialist.

Organized Science in the War Effort

Sir John Anderson told Mr. Stokes on August 6 that the Scientific Advisory Committee had not been asked to make a report on the organization of the higher direction of our scientific effort in the war. Certain representations to the Government by leading members of the Scientific Advisory Committee and Engineering Advisory Committee were under consideration.

Captain Plugge and other Members have tabled a resolution calling for a whole-time Central Scientific Technical Board.

Sale of Tuberculous Cows.—Mr. R. S. Hudson said on Aug. 6 that he was unaware that certain agricultural papers gave advice suggesting the sale in the local markets of cows suffering from tuberculosis and other infectious or contagious diseases. Slaughter with compensation, as in the case of foot-and-mouth disease, was impracticable.

Nervous Diseases and Army Service.—Captain York on Aug. 6 asked the Minister of Pensions to set up a research committee to consider what diseases, including epilepsy and petit mal, were brought on by Army service in cases where no previous history of the disease was evident Sir Walter Womersley replied that there were in being an adequate number of research committees and other expert bodies which he consulted on the connexion of various diseases with Army service. One of these committees was consulted at the outbreak of this war with regard to the diseases mentioned.

Civilian Doctors with the Army.—In a reply to Mr. Beaumont on Aug. 6, Mr. Duncan Sandys said that where civilian medical practitioners were employed full-time to look after sick military personnel, the latter had always an officer responsible for their administration and discipline. It was therefore unnecessary to grant honorary commissions to full-time civilian medical practitioners for this purpose.

Osteopaths.—Mr. Hannah asked on June 6 what public recognition was given to osteopaths and whether in the event of their being liable to service any use was made of their healing ability. Mr. Brown answered that in view of the recommendations in the report of the Select Committee of the House of Lords on the Osteopaths Registration and Regulation Bill, 1935, Parliament had not thought fit to confer any official recognition on osteopaths or to accord them any of the rights specially accorded to registered medical practitioners He understood that the Services did not make use of the special manipulative technique of osteopaths.

Notes in Brief

Accidents reported under the Factories Act in the last three months of 1939 were: 465 fatal, 68,980 non-fatal; in 1940 1,372 fatal, 230,607 non-fatal; in 1941 1,646 fatal, 269,652 non-fatal; in 1942 (January to June) 699 fatal, 153,087 non-fatal. The figures for 1942 are provisional and subject to correction.

Mr. Brown has under immediate consideration the release from the Emergency Hospital Scheme of a further 200 beds for tuberculosis cases in Wales.

The number of mental defectives under guardianship in England and Wales at January 1, 1939, and January 1, 1940, were 4,531 and 4,723 respectively.

Up to the end of June pensions had been awarded for disabilities in the gastro-intestinal group in slightly over 10,000 cases discharged from the Forces as invalids.

The number of disabled persons to whom pension is being paid by the Ministry of Pensions is approximately 448,000, of whom nearly 38,000 are in receipt of pension at the rate for total disablement. Included in the total figure are 32,500 limbless cases.

Medical News

Sir Harold Scott will retire on August 31, 1942, from the post of Director of the Bureau of Hygiene and Tropical Diseases which he has held since 1935. The Secretary of State for the Colonies has appointed Dr. Charles Wilcocks, the present Assistant Director of the Bureau, to be Acting Director, with effect from September 1, 1942.

The College of Physicians of Philadelphia awarded the Alvarenga Prize on July 14, 1942, to Dr. Edwin J. Cohn, Professor of Physiological Chemistry, Harvard University, in recognition of his distinguished contribution to our knowledge of blood proteins. This Prize was established by the will of Pedro Francisco DaCosta Alvarenga of Lisbon, Portugal, an Associate Fellow of the College of Physicians, to be awarded annually by the College of Physicians on each anniversary of the death of the testator, July 14, 1883, to the author of " the best memorial upon any branch of medicine, which may be deemed worthy of the prize."

The Minister of Health has concurred in a recommendation submitted to him by the Medical Personnel (Priority) Committee that teaching bodies should be advised to abandon for the duration of the war " all medical postgraduate courses which require whole-time attendance of medical men and women for a considerable period." In a circular letter to deans of medical schools asking that this recommendation should be brought before the management body, the Minister states that he holds the view that any student who is fit to follow such a course of instruction, even though he may perhaps be unfit or ineligible for military service, should undertake work of such a nature as would result in the release of another medical practitioner for service with His Majesty's Forces.

Dr. Elsie V. Crowe, F.R.C.S.Ed., is now officially presumed to be a prisoner of war in Sumatra.

Dr. Juan P. Garrahan, a Buenos Aires paediatrician, has been awarded the 1941 prize of the Buenos Aires National Academy of Medicine for his article on " Prothrombin, Vitamin A, and Haemorrhage in the Newborn Infant."

Dr. Rudolph Matas, emeritus professor of surgery at the Tulane University of Louisiana, has been presented with the medal of Havana, the highest distinction conferred by that city in commemoration of Dr. Carlos I. Finlay.

A French institute for human research has recently been founded in Paris in the building of the Rockefeller Institute, with Dr. Alexis Carrel as director.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week a reduced incidence was reported for each of the notifiable diseases with the exception of puerperal pyrexia, of which 6 more cases were recorded. The largest of the decreases were those of measles 341, acute pneumonia 61, diphtheria 60, scarlet fever 60, dysentery 37. The returns for cerebrospinal fever were the lowest since the first week of 1940, and the notifications of acute pneumonia were the lowest for almost a year.

The largest fluctuations from the totals of the preceding week for whooping-cough were those of Yorks West Riding, Middlesex, and Staffordshire, where increases of 47, 43, and 24 were recorded.

An increase in the incidence of measles occurred in London and Yorks West Riding, where the cases were 45 and 67 in excess of the previous week's total.

The notifications of dysentery, 64 cases, were the lowest weekly total since last August. The only local outbreak of any size was that of Birmingham C.B., 12 cases.

In *Scotland* the incidence of measles, which had been at a fairly constant level for a month, fell, and the lowest weekly total since the end of February was recorded. Of the 52 cases of dysentery 25 were notified in Edinburgh.

In *Belfast* the epidemic of measles appears to be ending; 74 cases were notified compared with 118 in the preceding week.

Small-pox

No further cases of small-pox had been notified in Glasgow during the beginning of the month. The total cost incurred by the city as a result of the outbreak is estimated to be between £50,000 and £60,000.

Returns for the Week Ending August 8

The notifications of infectious diseases in England and Wales during the week included the following number of cases: scarlet fever 1,340, whooping-cough 953, diphtheria 580, measles 5,619, acute pneumonia 413, cerebrospinal fever 77, dysentery 82, paratyphoid 15, typhoid 6.

No. 30

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 1.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)
Cerebrospinal fever ..	69	5	28	2	2	147	8	34	1	5
Deaths		—	1				1	—		
Diphtheria	650	33	161	65	13	821	38	126	20	22
Deaths	12	—	2	1	—	20	—	2	1	—

QUERIES AND ANSWERS

Blood Injection in Tuberculosis

Dr. J. H. FLETCHER (Merthyr Tydfil) writes: May I use your columns to inquire whether any attempt has been made in the cure of tuberculosis to administer to the patient repeated systematic intramuscular injections of blood (of same blood group) as that of the patient) taken from a cured person or from a healthy individual whose family history shows no evidence of the disease, with the object of transferring the immunity from the cured or healthy to the sick, as is now advocated and practised in the treatment of measles?

Castor Oil in Infective Hepatitis

Dr. E. K. RULE (South Perth, Western Australia) writes: It was with interest that I read Dr. J. L. Newman's article on an outbreak of infective hepatitis in the Lavant Valley (Jan. 17, p. 61). I should be glad to know if the doctors in charge of these cases made any observations with regard to the administration of castor oil. While staying at a country town in Victoria recently I encountered a similar epidemic, and my own family and those of my neighbours suffered from the disease in varying degrees. In all of those cases in which castor oil was administered I noticed that the patients became rapidly worse and signs of biliary obstruction supervened, whereas there was no such sudden change in those not receiving castor oil. In the former the effect was so marked and the appearance of the clay-coloured stools so immediate that I felt convinced it was the castor oil which at least precipitated the obstructive symptoms. If this observation is confirmed it would seem to have an important bearing on preventive treatment, since castor oil is so frequently administered to children suffering from nausea and vomiting.

Income Tax

Service Pay: Basis of Assessment

T. N. is assessed for 1941-2 on (*a*) his civil earnings for the year 1940-1, and (*b*) his official emoluments for the year 1941-2. Is this correct?

⁂ Yes. As the Service appointment did not begin until August, 1940, 1941-2 is the second financial year since commencement, and by statute tax on the emoluments is chargeable on the basis of the current year's earnings. As the civil earnings are regarded as coming from a continuing source, the legal basis is the previous year—which will, of course, continue to apply if and when T. N. returns to the practice.

LETTERS, NOTES, ETC.

Quinine in Malaria

Dr. R. J. MARSHALL writes: During the four and a half years spent by me in Spain from 1893-8 as assistant medical officer to the Rio Tinto Co., part of my time was taken up in studying microscopically the various types of malarial fever so prevalent there. They were principally of the benign type, tertian and quartan I found that the best results in treatment were obtained by administering quinine in *one* daily dose of 30 grains about 2 hours before the expected rigor. This is following the advice of the Italian observers Marchiafava and Bignami, whose book was published by the Sydenham Society. According to them the young parasites are most vulnerable at the moment of birth. I seldom found a dose of this size cause any unpleasant symptoms, and the results were much more effective than when the drug was given in divided doses. This can easily be verified experimentally in a case where there is a double infection. A single dose of 10 grains given 2 hours before one attack may for several days cut out a recurrence of this attack or modify it considerably without affecting the other.

Scabies

Dr. W. F. BENSTED-SMITH (Newton Ferrars), writes: It may be well to call attention to a common and often unrealized centre of infection—the local dance hall. I am impressed by the number of cases in clean homes which are possibly contracted in this way. It probably accounts also for a number of those infected on leave.

An Interesting Breech Delivery

Dr. W. L. MACDONALD (Charlottetown, P. E. I) writes: I was called one night about 2 a.m and informed by an excited woman that Mrs. A. had her baby while sitting on the toilet seat. I asked her to get the baby out before it drowned. She said she couldn't get Mrs. A. off the seat. I dressed, drove about a mile to the house, and found Mrs A. still sitting on the toilet. On helping her off I found the baby head-first in the toilet water, blood, etc. After extracting the baby feet first and giving it a slap on the bottom, I was much surprised to hear it give a lusty cry. Its life was saved by the placenta remaining intact *in utero*, and the cord not breaking.

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* for August 20, 1842:

" The Chairman said he had next to call on them to drink a toast to which he anticipated a prompt and most enthusiastic response —it was that of the founder of the Association, Dr. Hastings. When they remembered that ten years ago the members of the medical profession in the provinces were without any common bond of union (hear, hear) ; that although they possessed within themselves the elements of great strength, of moral energy, and of high character, yet these were of little use, because they were never found joined together for any practical purpose (cheers) ; when they remembered, also, that it was to Dr. Hastings they owed the formation of this great Association in which, for the first time, they had found that bond of union which they had long so much required—which had given to them an amount of influence, and produced among them a degree of harmony which had never before existed—which had the effect of bringing together the members of the same profession from one end of the kingdom to the other to meet at some common point, where, old friendships were renewed and new friendships formed, never afterwards to be forgotten—which had furnished them with an inducement sufficiently strong to draw them for a season from their homes, in order that they might interchange feelings of mutual friendship and good will, and unite not merely to uphold the honour and dignity of the profession, but also for the more extended diffusion of scientific knowledge, and so to benefit mankind; when, he repeated, they bore in mind that it was to Dr. Hastings, the secretary and founder of the Association, that they owed these manifold advantages, he was sure they would need no stronger motive to induce them to drink this toast with all the honours which it was possible for them to bestow upon it. (The toast was drunk with the most enthusiastic cheering, which was repeatedly renewed.)

In his reply Dr. Charles Hastings said, among other things, " It is a proud distinction to me to be considered the founder of this noble institution ; and when ten years ago I commenced, in conjunction with many friends I now see around me, the formation of this Association, I little dreamt of its ever attaining the eminence it has already acquired. During those ten years, Sir, our Association, like the noble oak of the forest, has struck its roots deeply into the midland counties, and has thrown out vigorous branches to the north and to the south, to the east and to the west During this comparatively short period what have we done? I am aware that this question has been sometimes asked tauntingly—but what have we done? We have every reason for answering this question ; not indeed in the spirit of self-glorification, but with truth and modesty, in order that we may place our claims to public confidence on their true footing In reply, we have every year published a volume of " Transactions," and that these ten volumes form a rich treasury of practical information ; and more especially, we have done more towards accomplishing that very desirable object, the procuring a medical topography of England, than had previously been effected. We have thus, in a scientific point of view, raised the character of the provincial profession, who heretofore, notwithstanding many eminent men had arisen among them, had no claim as a body to any distinction. We have also, during the last year, succeeded in supplying to every member of our Association a weekly journal [the *Provincial Medical Journal*, forerunner of the *British Medical Journal*] as a vehicle by which all discoveries made in this active and experimental age are conveyed to the remotest villages in England, and a boon is thus conferred on suffering humanity."

Taken from an account of the dinner held at the anniversary meeting of the Provincial Medical and Surgical Association in Exeter.

LONDON SATURDAY AUGUST 29 1942

A CLASSIFICATION OF NERVE INJURIES

BY

H. J. SEDDON, D.M., F.R.C.S.

Nuffield Professor of Orthopaedic Surgery, University of Oxford

In 1863, during the fiercest days of the American Civil War, Dr. W. A. Hammond, Surgeon-General to the Federal Armies, ordered the establishment of a unit for the observation and treatment of injuries of the nervous system. A signal result of this instruction was the appearance in 1864 of a little book by Weir Mitchell, Morehouse, and Keen, *Gunshot Wounds and Other Injuries of Nerves.* This gave an account of the first organized study of nerve injuries, and in it we find not only the most perfect description of causalgia, a condition that will always remain associated with the name of Weir Mitchell, but descriptions of nerve injuries as we see them to-day. These enthusiastic workers laid a good foundation for all that has followed during the succeeding 80 years. But the means of investigation at their disposal were very limited, open operations were rare, and the syndromes described are not quite sufficiently clear-cut to serve as a guide in diagnosis and prognosis.

The enormous number of nerve injuries dealt with during the last war gave to neurologists and surgeons a very clear conception of the results of division of a nerve, but one gets the impression that they were so preoccupied with the repair of nerves so seriously damaged as to require resection and suture that there was hardly time to investigate the great mass of cases in which something less than complete division was present, cases in which spontaneous recovery usually occurred. So far as nerve injuries are concerned this war has been more leisurely.

It is the purpose of this preliminary communication to describe three well-defined types of nerve injury, types so distinctive that it has been found convenient, and indeed necessary, to apply labels to them and make them the basis for a clinico-pathological classification. It might be foolish to claim that every nerve injury can be fitted into this classification, but from the study of 460 cases at the Oxford Centre it has become evident that the majority can be so classified provided one realizes that a combination of lesions is not infrequently present as the result of a single injury.

Clinical Signs of Damage

The clinical manifestations of damage to a peripheral nerve may be considered under two headings.

1. *Those due to Loss of Function:—*

   Efferent: Paralysis of muscles; sudomotor paralysis: pilomotor paralysis; vasomotor paralysis.

   Afferent: Loss of tactile sensibility; loss of pain sensibility; loss of thermal sensibility; loss of joint and postural sensibility; loss of deep sensibility.

2. *Those due to Perversions of Function:—*

   Efferent: Muscle twitching (fasciculation); muscle spasm; abnormal sweating; vasomotor disturbances.

   Afferent: Paraesthesia; apparently spontaneous pain, and pain quite outside the range of normal experience; abnormal responses to heat and cold.

In contemporary clinical practice there is no question whatever that in frequency and importance the first group of phenomena far outweigh the second, and it is with loss of function alone that this classification is concerned.

Although, as has been said, there is a fairly clear understanding among clinicians and experimental workers about the sequence of events following complete anatomical division of a peripheral nerve, there is considerable confusion when we come to examine those numerous cases in which function is lost although anatomical continuity of the nerve is more or less preserved. No clear distinction has been drawn between those intraneural lesions that are followed by complete peripheral degeneration and those in which the rate of recovery is so rapid that degeneration could not possibly have occurred. The well-known term "physiological interruption" conjures up no clear pathological picture, and it is inaccurate in that no interruption of conductivity can properly be called physiological. Similarly, the terms "concussion," "compression," and "contusion" are equally vague; for although they may give a hint of the nature of the cause they do not describe the effect of the injury on the nerve itself.

At a meeting of the Association of Physicians held in April, 1941, I propounded the following classification:

1. Complete anatomical division of a nerve.
2. A "lesion in continuity," in which more or less of the supporting structure of the nerve is preserved but there is nevertheless such disturbance of the nerve fibres that true Wallerian degeneration occurs peripherally.
3. "Transient block."—A minimal lesion producing paralysis that is incomplete more often than not; it is unaccompanied by peripheral degeneration and recovers rapidly and completely.

These three syndromes are well known to neurologists, and discussion centred chiefly on terminology. It may be argued with justification that "lesion in continuity" is ambiguous and might well include "transient block": for there is no doubt that in transient block the nerve is in continuity. It was therefore suggested by Prof. Henry Cohen that distinctive names should be given to these three types of nerve injury so that confusion might be avoided. He writes:

"Etymologically these words indicate the ideas they are intended to convey, and they have not previously been used—so that the field for them is clear.

"1. *Neurotmesis* (τμῆσις, a 'cutting' which implies a separation of related parts), which describes the state of a nerve that has been completely divided. The injury produces a lesion which is in every sense complete.

"2. *Axonotmesis:* Here the essential lesion is damage to the nerve fibres of such severity that complete peripheral degeneration has followed; and yet the sheath and the more intimate supporting structures of the nerve have not been completely divided, which means that the nerve as a mass of tissue is still in continuity.

"3. *Neurapraxia* (ἀπραξία, non-action) is used to describe those cases in which there is a short-lived paralysis—so short that recovery could not possibly be explained in terms of true regeneration."

4260

The classification is partly morphological, though in each case the clinical behaviour is characteristic. The three types of lesion have been produced experimentally, and work of this kind has contributed considerably to our understanding of them.

It is not proposed here to give more than an outline of the characteristics of the three types, since full descriptions will be published shortly (by me, on neurotmesis, axonotmesis, and neurapraxia; and by W. B. Highet on mixed and incomplete lesions, which are grouped together as *dissociated* paralyses). The classification is presented in brief in the hope that it will prove helpful to clinicians in sorting out their cases of nerve injury.

Neurotmesis (Division of a Nerve)

The clinical and pathological picture presented by complete division of a nerve is so familiar that no more than the briefest description is necessary. At the *site of damage* a swelling which is called a "neuroma" appears at the end of the central stump; it consists of a mass of scar tissue and new nerve fibres in no way different from what is seen in an amputation neuroma. The swelling is sometimes palpable and tender. A swelling also appears at the end of the peripheral stump; it is called a "glioma," is composed of Schwann cells and fibrous tissue, is much smaller than the neuroma, and is rarely palpable clinically.

In the *distribution of the nerve* there is complete sensory and motor paralysis; the affected muscles degenerate and waste, and respond to electrical stimulation with the characteristic reaction of degeneration. The only difficulties in diagnosis are anatomical—in cases where some anomaly in distribution may lead the clinician to believe that the lesion is an incomplete one.

For all practical purposes recovery never occurs in the absence of surgical repair. If suture is followed by regeneration, signs of recovery appear in anatomical order; this is best seen on the motor side, where a regular march of recovery in muscles is often observed. The quality of recovery is always short of perfect, not only because of irreversible degenerative changes in end-organs and muscle but because of confusion at the suture line.

Axonotmesis (Lesion in Continuity)

If a nerve is crushed heavily with forceps all the nerve fibres are broken, but the connective tissue of the nerve survives to some extent; although the gap in the nerve fibres may be quite noticeable at first it is followed by a flowing together of the fibre protoplasm above and below, so that when observed a few minutes after removal of the instrument the lesion, which at first was nothing more than a thin ribbon of connective tissue joining central and peripheral stumps, has filled out to almost normal diameter. There is probably no case in which the connecting function of connective tissue is of greater importance; for it is found that, although the peripheral stump degenerates completely, spontaneous regeneration invariably follows after such an experimental lesion.

Now, it often happens that a nerve is damaged in a somewhat similar way by a "near miss," or pressure from one of the fragments of a fractured bone—in fact, by any injury that fails to divide the nerve completely. It is not to be expected that the accidents of daily life or warfare produce lesions as uniform as those produced in the laboratory: the nature and degree of violence are variable, and so is the extent of the damage done. The lesion exposed at operation may be the familiar fusiform neuroma or nerve spindle: more frequently (as in the experimental lesion) there is little to see beyond slight swelling or constriction, perhaps perineural adhesions and a little thickening of the epineurium. However, in general, the behaviour of lesions of this type is characteristic. The lesion is called "axonotmesis" because its essential feature is complete interruption of nerve fibres with preservation of more or less of the supporting structure of the nerve. After a period of several weeks or a few months new fibres manage to make their way through the scar tissue at the site of the lesion, and regeneration then proceeds in an anatomically orderly fashion down the peripheral stump. In experimental animals (rabbits) the rate of regeneration is faster after axonotmesis than after neurotmesis, but we are not yet sure that this is the case in man, although there is some evidence to suggest it. What is quite certain is that functional recovery is far better, and it is reasonable to suppose that this is due to the growth of fibres into their old pathways; some of them may go astray, but the majority are guided by the endoneurium and perineurium into their old channels. Everyone is familiar with the excellent spontaneous recovery that generally follows radial paralysis complicating fractures of the humerus, and this is the best example of axonotmesis in clinical practice.

It cannot be emphasized too strongly that there is no clinical difference whatever between the paralysis resulting from axonotmesis and that following neurotmesis. Seeing that peripheral degeneration is complete one could not possibly expect to find any, and indeed there is none. How, then, are the two conditions to be distinguished? There are three possible ways.

Experience teaches us that certain injuries are likely to cause neurotmesis, while others are more likely to cause axonotmesis. Radial paralysis complicating a gunshot wound of the arm is likely to be due to neurotmesis, in which case recovery will not occur unless the nerve is sutured. On the other hand, a closed fracture of the humerus involving the radial nerve almost always produces axonotmesis: by the time treatment of the fracture is completed there is generally some sign of recovery. On can therefore make a shrewd guess from knowledge of the nature of the injury. The second way is to wait until sufficient time has elapsed for spontaneous regeneration to occur. If signs of recovery fail to appear, then neurotmesis may be suspected and the nerve should be explored. This has been the general policy in the past, but the time of waiting has been too long; it is clear that if the lesion is in fact neurotmesis valuable months will have been wasted. No harm comes from exploring a nerve, and it has become our practice to carry out exploration in every case in which regeneration has not appeared within the calculated time.* This brings us to the third and only precise method—i.e., exploration. Riddoch has repeatedly emphasized that we should regard operative exposure of the lesion as a necessary step in the establishment of the diagnosis. Provided that the operation is carried out by a competent surgeon who is familiar with every detail of the neurological picture, and provided his approach to the nerve lesion itself is conservative rather than radical, exploration is a commendable procedure. It may reveal a somewhat unexpected neurotmesis; it may reveal axonotmesis, in which case the surgeon and the patient know what to expect —i.e., spontaneous regeneration.

Neurapraxia (Transient Block)

Recovery from certain nerve injuries is remarkably rapid—indeed, so speedy that it cannot possibly be explained in terms of axonal regeneration. Lesions of this type, like axonotmesis, may be produced by any injury that does not actually sever the nerve, but the violence is not of a high order. Tourniquet paralysis, Saturday-night paralysis, crutch paralysis, are all familiar examples—though sometimes these injuries may be sufficient to produce true degenerative changes.

Since the condition is essentially a clinical syndrome it is best to describe its clinical characteristics first: (*a*) the paralysis is predominantly motor; (*b*) there is little wasting; the electrical reactions of the muscle persist unchanged; (*c*) subjective sensory disturbances—numbness, tingling, pins-and-needles, burning—are common; (*d*) objective sensory disturbances are generally partial, often minimal, so far as touch, pain, heat, and cold are concerned; (*e*) loss of postural sensibility and vibration sense are common; (*f*) loss of sweating is unusual. Muscle tone is said to be retained, but this has not been our experience.

It is clear, then, that the lesion is a dissociated one: the motor and proprioceptive fibres suffer more than those subserving other functions, and there is a physiological explanation for this. Recovery, which can be predicted with absolute confidence if examination reveals this syndrome, is fairly rapid, beginning usually after two to three weeks and complete within six to eight—though I have seen a few cases in which complete restoration of function was delayed until the fourth month. The progress of recovery is irregular;

---

* A paper dealing with rates of regeneration will be published within the next few months.

it follows no anatomical order—it may appear suddenly throughout the whole distribution of the affected nerve, and resembles nothing so much as the wearing off of the effects of local anaesthesia. In the few cases in which it is delayed it is still much more rapid than the fastest recovery from axonotmesis, and would demand a rate of growth of axons quite unknown in clinical or laboratory experience. Furthermore, the preservation of normal excitability of muscles is clear evidence against Wallerian degeneration of the nerve below the lesion, and we now have evidence on the motor side that the affected nerve is not only capable of conducting impulses but in fact does so, though no contraction of the muscle can be detected clinically. There is therefore a disturbance of conduction (which can be produced experimentally) that impedes the transmission of impulses but does not destroy the axon. Recovery is always perfect.

Neurapraxia is a non-committal but adequate description of this non-functioning of a nerve. Neurapraxia is produced by cocainization of a nerve, by mild degrees of refrigeration, and by slight injury.

Comment

It is obvious that by no means all nerve injuries can be classified under these simple headings; the accidents that produce them are not uniform in their effects unless the violence is great. An injury may affect the fibres of a nerve in varying degree, and the clinical picture will then be more complex. A lesion may be made up by a combination of any of the following: (*a*) neurotmesis; (*b*) axonotmesis; (*c*) neurapraxia; (*d*) normal fibres.

Indeed, neurapraxia is a lesion in which a certain number of normally functioning fibres are always present. Leaving this aside, there are no fewer than eleven possible combinations of these lesions, each with its own clinical characteristics! In complicated lesions of the brachial plexus, for example, the picture may be so mixed that precise diagnosis is impossible, though there is often plenty of scope for light-hearted speculation. We have seen almost every one of the possible combinations, and do claim that none of the phenomena of interruption of a nerve that we have so far encountered required other explanation. This is a very difficult field of clinical inquiry, and it is not proposed to discuss it here, seeing that the various combinations of lesions form the subject of a paper that will shortly be published by W. B. Highet, who has investigated all the cases of dissociated paralysis seen at the Oxford Centre since its inception in June, 1940.

CAROTINAEMIA

BY

S. ALMOND, M.D., M.R.C.P.
Honorary Assistant Physician, Salford Royal Hospital, Honorary Physician, Manchester Victoria Memorial Jewish Hospital; Consultant Physician, Leigh Infirmary

AND

R. F. L. LOGAN, M.B., Ch.B.
Resident Medical Officer, Salford Royal Hospital

We have recently observed 5 cases showing pigmentation of the skin pronounced enough to warrant provisional diagnoses, by the attending practitioners, of "jaundice," "pernicious anaemia," "haemolytic anaemia," and "cholelithiasis." This pigmentation can only be properly described as "carroty," and while in the mild cases it is most obvious in the naso-labial folds and the palms of the hands, in the more advanced cases it is a generalized body tanning. The condition is due to the excessive consumption of carrots, though it has been recorded when other lipochrome foods are eaten in quantity.

The Literature of Carotinaemia

The term "carotinaemia" for the orange pigmentation of the skin observed after the excessive consumption of carrots and other vegetables was first applied by Hess and Myers in 1919. The observation of this skin discoloration in diabetics whose diet consisted mainly of foods rich in yellow lipochrome—fruit, vegetables, butter, and eggs—was made by von Noorden (1907), who considered the condition to be a diabetic manifestation. Moro (1908) noted that normal infants developed a similar pigmentation when carrots were added to the diet. Van den Bergh and Snapper (1913) showed that there were lipochrome pigments circulating in the blood of diabetic patients with the orange pigmentation, and that these pigments were identical spectroscopically with those of carrots and other vegetables. Salomon (1919) referred to this pseudo-icterus in non-diabetic patients whose diet largely consisted of the foods mentioned, and the gradual disappearance of this pigmentation with abstinence from such foods. Stoeltzner (1919), commenting on Kaupe's observation (1919) that nurslings lost their yellow coloration when their high carrot diet was stopped, observed that the number of similar children had increased during the last war. He called it a "pseudo-icterus" and thought a high tomato diet might produce a similar pigmentation.

Greene and Blackford (1926) and Stoner (1928) discussed the condition under the heading of "carotinaemia." Boeck and Yater (1929) used the term "xanthaemia" for the circulation in the blood of lipochrome pigments (thereby excluding bile pigments) and "xanthosis" for the visible presence of these yellow pigments in the skin. They found xanthaemia in all their nephritics and in most diabetics, and even in most "normal" cases examined. However, xanthosis was present in only 10% of the renal and diabetic cases and in only 3% of other cases. All these patients with stained skin had eaten excessively of lipochromic foods.

Stannus (1929) called the discoloration "hyperlipochromia," and concluded that it resulted from the failure to oxidize the carotinoid pigments in the body. He first reported carotinaemia in myxoedema, and Wendt (1935) noted the condition in some cretins. Bomford (1938) confirmed the presence of carotinaemia in some cases of myxoedema on a normal diet. On thyroid medication the lipochrome index fell to normal. He remarks that as the colour of cream is due to lipochromes, the description of the myxoedematous facies as a "strawberry and cream" complexion is not without justification.

The Present Series of Cases

Our interest in carotinaemia was first aroused by the visit of a clerk's wife on account of "jaundice," though her sclera was contrastingly white. In the spring months further cases were referred as "pernicious anaemia" and "haemolytic anaemia"; the woman with "gall-stones" was visiting her husband, an in-patient with acute nephritis, when the ward sister drew our attention to her carroty complexion. None of these patients had symptoms of ill-health, though the curious discoloration was a source of anxiety.

Careful histories were extracted to find the actual pounds of carrots consumed per week (see Table). As kitchen standards of quantity are given vaguely in pinches, spoons, and cups, we sought and obtained the number and size of the carrots, from which a correct estimate was made. These weights apply only to the raw carrots, as the other vegetables and cooked carrots were always eaten in pre-war helpings. During the

Corporal	Haemolytic anaemia	4	8	+	8	0·1	2	5	Microcytic anaemia
Baby ..		breast-fed	2	—	—	—	4	8	Healthy

winter carrots were cheap and easily obtainable, and "besides, they were so nice to munch." The lorry-driver's wife had been told "carrots were full of vitamins." The clerk grew so many carrots on his allotment that his wife felt she had to eat them. She liked the clean taste left in her mouth so much that she invariably carried one about in her pocket. Since June of last year the corporal's wife used to munch carrots, especially while preparing the family meals, in order to increase her vitamin intake during her period of gestation. A healthy baby was born at Christmas and thrived on the breast. It had no other treatment. In February the corporal noticed his wife and baby were carroty and sought his doctor's advice. Jaundice was diagnosed and the breast dethroned by the bottle. On a light diet and milk feeds the pigmentation gradually faded.

The time taken for saturation before the carroty skin was first noticed is tabulated as the threshold months. Each patient was thoroughly investigated for diseases which may have provided other factors; but they were quite healthy women, apart from one moderate case of mitral stenosis and the almost invariable hypochromic anaemia so prevalent in this area. These patriots of the "Kitchen Front" were congratulated on their heroic consumption both of carrots and of propaganda, and were asked to return to their basic helpings of vegetables, including carrots. On this moderation (it was not abstinence) the times in weeks of initial and then complete fading were noted.

Our threshold value corresponds approximately to that of a patient, quoted by Wood and Agnor (1941), who ate two carrots daily for a year. Kaupe's (1919) finding of carotinaemia in babies weaned on carrot soup, the lipochrome content of which must necessarily have been small, is in harmony with our baby's susceptibility in developing skin pigmentation after only two months on the breast milk of its carotinaemic mother. This is believed to be the first case reported of carotinaemia from the breast milk of an affected mother.

Laboratory Investigations

The routine estimations of icteric index and serum bilirubin were carried out in all cases. These revealed an obviously "jaundiced" serum of a high icteric index (on colour comparison with the potassium dichromate standard 1/10,000 dilution) but a serum bilirubin within normal limits. Obviously the orange colour was not due to bile pigment. However, the lipochromes are soluble in petroleum ether and the bile pigment in absolute alcohol, which will also precipitate the proteins in the serum.

This fact forms the basis of the test of Greene and Blackford, which we refer to as the three-layer test, to differentiate carotinaemia from jaundice. Equal quantities of serum, alcohol, and petroleum ether are shaken up in a tube. This may be left to settle, as the volatile petroleum ether, with its dissolved lipochromes, rises to the top as a distinct layer. If lipochromes are present in abnormal amount this top layer will show a definite yellow tinge which is pathognomonic of carotinaemia. The depth of colour may be compared with the potassium dichromate standard to give its lipochrome index. However, it is better to centrifuge the mixture in the tube. The precipitated proteins spin down to the bottom as a white curd, covered by the middle band of absolute alcohol with its dissolved bile pigments, on which the "true icteric index," or bile index, can be estimated against the dichromate standard. If this middle alcohol band is excessively yellow and is covered by a clear petroleum layer, then the sandwich is jaundiced and the bile index will equal the icteric index.

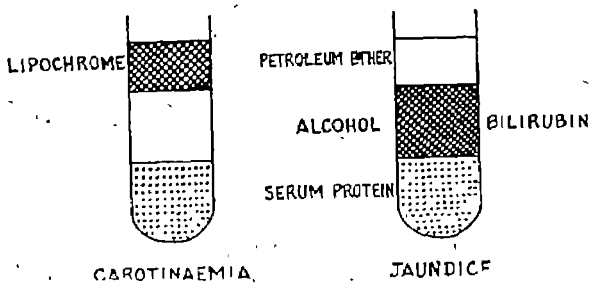

Diagram illustrating the three-layer test for the differentiation of carotinaemia from jaundice.

Icteric index	=	*Bile index*	+	*Lipochrome index*
(on whole serum)		(on alcohol layer)		(on ether fraction)

In a hypothetical case of jaundice and carotinaemia both layers will be quite yellow, and the degree of each pigmentation can then be estimated separately.

Carotene is the yellow colouring matter—the lipochrome—of carrots, spinach, palm oil, and nettles. It is a highly unsaturated hydrocarbon, $C_{40}H_{56}$, which exists in three forms—alpha-, beta-, and gamma-carotenes. These can be separated by filtering a light petroleum solution through a Tswett column of calcium hydroxide. Each form adsorbs out of solution at a different layer in the column. All three forms are precursors of vitamin A, but owing to its internal pattern one molecule of beta-carotene yields two molecules of the vitamin, while the alpha and gamma forms produce only one molecule. Thus the beta form has twice the physiological activity of alpha- and gamma-carotenes. Natural products, however, contain much more beta- than alpha-carotene and little, if any, of the gamma form. The isomer of carotene is lycopene, which is the colouring matter of tomatoes, rose hips, and bittersweet berries, but is inactive physiologically in not forming vitamin A. Carotene is the principal though not the only lipochrome in human serum. It is always associated with its hydroxyl derivative, a xanthophyll. Lutein is the xanthophyll of alpha-carotene, and is the lipochrome in egg yolk and green leaves. Thus the term "xanthaemia," of Boeck and Yater (1929) is more accurate than the popular carotinaemia.

The absorption of the lipochromes from the bowel is stated by Wood and Agnor (1941) to depend on the presence of dietary fat and the bile acids with which it is absorbed as a water-soluble diffusible complex. Curtis and Ballmer (1939) have shown that liquid paraffin interfered with this transport of carotene across the epithelium of the intestine. In the plasma the carotene is probably adsorbed to the albumin molecule and carried in colloidal suspension. The plasma proteins can be precipitated down by absolute alcohol, which itself dissolves bile pigments, while the lipochromes are soluble in petroleum ether, which floats lightly as a separate layer above the alcohol. This provides the basis for the three-layer test of Greene and Blackford. The conversion of carotene into vitamin A probably takes place in the liver.

Ralli *et al.* (1936) showed that the liver of a carotinaemic diabetic contained an increased amount of carotene. Pariente *et al.* (1936) theorized that in diabetes the conversion of carotene to vitamin A was impeded and that this resulted in a damming up of carotene in the liver and a diminished absorption from the blood. They neglected the additional factor of the high lipochromic diet usual in diabetics.

According to Wood and Agnor (1941), any excess of carotene is either destroyed or excreted via the sweat. They state that when excretion is unusually heavy the carotene is reabsorbed by the horny layer of the skin. Palmer and Kempster (1919) found the lipochromes in fowls in the rete malpighii and cornified layers of the skin. Greene and Blackford (1926) observed the concentration of pigment in the naso-labial folds, where sebaceous glands abound, and in the palms and soles, where cornified skin is thickest. We find that the soles of Lancashire housewives are undistinguished, but that the palms of our hospital cooks, after scraping carrots for dinner, were stained like T.N.T. workers. However, this direct staining from handling carrots could be washed off almost completely—in contrast with that from excessive intake, which was undiminished by washing. In our cases, in addition to the naso-labial folds and palms, the rest of the skin was almost uniformly tanned, but the sclera was contrastingly white. This immunity of the sclera in carotinaemia is the chief clinical sign in differentiating it from jaundice. The colour of the skin and the details of food intake are additional factors in clinical diagnosis.

Several of our patients noticed a deep orange colour in the urine. Attempted extraction of the colour with petroleum ether was unsuccessful, and no typical absorption bands were found spectroscopically.

Boeck and Yater (1929) discuss the wide variation in the appearance of xanthosis and xanthaemia in individuals on similar diets. To account for this, they believe that the rates of oxidation and excretion must vary widely. Bernheim (1926) fed large quantities of carrots to 3 patients, who quickly produced a high icteric index, which, however, fell to normal within 12 hours. In our cases the rate of metabolism seemed to be remarkably constant in the different individuals. The threshold quantity appeared to be a minimum of 4 lb. of excess carrots per week for a minimum period of seven months before skin pigmentation became visible. The rate of fading appeared to be equally constant once they returned to an average diet. Fading was first noticed in a minimum of two weeks and was complete within eight weeks. In view of Bernheim's finding of the rapid disappearance from the blood of excess lipochromes within 12 hours, it would seem that above the threshold quantity the body is unable to oxidize or excrete all the lipochrome, so that some pigment is slowly accumulating. The capacity of the body to eliminate lipochromes must be well above the normal requirements, as it takes a minimum of six months' accumulation before the high threshold is reached on such abnormal intake and before skin pigmentation is noticeable.

The findings of the remarkably constant threshold in the accumulation of pigment and of the steady rate of fading in normal individuals support the theories of diminished conversion of carotene to vitamin A in the liver of diabetics and poor urinary excretion in nephritics, as in both diseases carotinaemia occurs more frequently than in health.

Summary

Carotinaemia is a carroty pigmentation of the naso-labial folds and palms when mild and, when marked, a general body tanning except in the sclera, which distinguishes it clinically from jaundice. It is due to the excessive consumption of carrots and other lipochromic foods. The patients are healthy and do not require treatment apart from reduction to average consumption.

Four cases of carotinaemia are described in normal women after eating more than the threshold quantity of 4 lb. of raw carrots per week for a minimum period of seven months.

A baby fed only on the breast of its carotinaemic mother developed the condition within two months. This is believed to be the first case described.

The simple three-layer test of Greene and Blackford to differentiate between carotinaemia and jaundice is described.

We are indebted to Drs. S. Smithson and M. C. Welsh for allowing us to see and investigate their cases. We wish to thank especially Dr. M. L. Thomson for permission to investigate the case of the infant of the carotinaemic mother.

W. E. Snell (*Tubercle*, 1942, **23**, 101) maintains that garden work is the main form of occupation for sanatorium patients for the following principal reasons: (1) it provides controlled exercise for patients under open-air conditions, and thus hardens them for return to a working life; (2) it relieves the boredom of institutional life and should provide the patient with a mental interest; and (3) the patient's labour theoretically provides some return to the institution. In any sanatorium of 300 beds about 50 patients will be available for garden work, consisting of the following groups of cases: (1) early or pleural cases for which no collapse therapy is indicated; (2) patients undergoing artificial pneumothorax and those convalescent from thoracoplasty; and (3) patients not suitable for artificial pneumothorax but whose general condition is good.

BEE-STINGS IN KENYA COLONY

BY

A. J. JEX-BLAKE, M.D., F.R.C.P.*

East Africa is a good place for studying the effects of bee-stings, because people living there are stung more often than those in England. This is in part because the common native bee, *Apis mellifica adansoni*, is more savage and eager to attack than the honey-bee of Europe, *Apis mellifica*, its near relative—for example, an expert bee-keeper of my acquaintance would often get as many as 50 stings a day while looking after her few hives of native bees—and in part because the bee population is large, the native inhabitants being apt to put up barrels, hollow pieces of tree-trunks, boxes, and other contraptions in trees anywhere and everywhere for the wild bees to hive in, the honey being used for beer-making. Further, these bees swarm all the year round, so that there is never a day when flying or settled swarms may not be met with out of doors or indoors. Finally, many East African houses, especially those that have been unoccupied for a time, acquire nests of bees in roofs, hollow walls, or under the floors that are very hard to get rid of when the house is occupied again. When they do attack, nests, hives, or swarms of native bees are apt to do so on the heroic scale. This is illustrated by the following 3 cases occurring in European settlers:

Cases of Massive Stinging: Recovery

Case 1.—A small man aged 75 was attacked by a swarm of bees in his garden. Between 200 and 400 stings were removed from his face and neck, and he was given an intravenous injection of 2 pints of 2% sodium bicarbonate solution. He showed no reaction from either the stings or the treatment, and no severe signs or symptoms.

Case 2.—A man aged 64 was attacked by swarms of bees and heavily stung about the face, neck, and hands. In 2 or 3 minutes he was overcome by violent diarrhoea and vomiting, and soon after that became unconscious. He was presently rescued and came to himself quickly. His face was so beset with upstanding bee-stings that he said he looked as if he had not shaved for 3 or 4 days. Over 300 bee-stings were extracted, and ammonia solution was dabbed on. He slept well with a sedative, and next day, apart from a little thickening and itching of the skin of the face and hands, felt quite all right.

Case 3.—A young woman set upon by swarms of bees was badly stung; she had attacks of diarrhoea and vomiting, and was rescued in a fainting condition. The number of stings extracted from her scalp, face, neck, chest, back, arms, and legs was at least 500, probably more—an hour and a half's work, including extraction of a sting from the very back of the tongue. Fine curved entomological forceps were used, and care was taken not to squeeze the venom-sacs during extraction. Dilute ammonia was applied, and the patient required a sleeping-draught and morphine. She kept to her bed next day and then recovered rapidly.

The numbers of the stings removed in these instances are those estimated by the medical men who removed them or by other observers, and there is no reason to believe that they have been exaggerated. The amount of venom injected by a single bee-sting is said by Phisalix (1922) to be 0.33 mg.: its active constituent is a protein. Case 1 suffered no more than a severe but passing inconvenience from the stings and must have had an exceptionally high tolerance of or immunity to bee-stings; Cases 2 and 3 can probably be taken as having the normal degree (if there is such a thing) of sensitiveness thereto.

Two Fatal Cases

The following two cases illustrate the fact that a man who has suffered no more than the normal transient local pain and swelling after bee-stings all his life may suddenly become hypersensitive to bee venom and be very near to death or even die when stung again.

Case 4.—A healthy man aged 45, passed fit for insurance 6 weeks previously, was stung 4 or 5 times while driving a swarm of bees out of his veranda; these stings gave rise to the usual transient painful swellings, as stings had done in previous years, but to no general symptoms. A fortnight later he was attacked by a swarm of bees while walking along a road, and was again stung on the face 4 or 5 times; he ran away, and in about 2 minutes collapsed and died. Artificial respiration, continued for an hour, was without effect.

Case 5.—This patient, a man aged 55, owned and lived on a sisal farm which chanced to have a particularly large bee population. For 20 years he had been stung at least a dozen times a year with no ill effects beyond slight and passing local swellings. A sudden change for the worse took place in this state of affairs. One day, while playing bridge on a veranda, he was stung in the leg. He felt very ill, collapsed in 2 or 3 minutes, was unconscious, cyanosed, and pulseless for 10 minutes, passed water and motions, and struggled violently on coming to. Twenty minutes later he was well enough to drive himself home in his car. During the next 9 months he had 10 more similar attacks on being stung; each attack was said to be more severe than the previous one. The last attack but one followed a sting on the forehead; the patient walked into the house, collapsed in half a minute, and was cyanosed and pulseless for 10 minutes. Two hypodermic injections of strychnine were given and the pulse slowly returned; while still unconscious the patient passed water and motions, as always happened in these attacks, had a violent rigor, and dripped with perspiration. He was placed on a couch and slept for 4 or 5 hours, waking up perfectly well. The eleventh and last attack followed a sting in the neck, and proved fatal in about 15 minutes.

Discussion

It seems reasonable to assume that in Case 4 the patient was sensitized or rendered hypersensitive to bee venom by the 4 or 5 stings he received a fortnight before his death. But in Case 5 there is, unfortunately, nothing to show why the patient suddenly became hypersensitive to bee venom 9 months before he died, after having been quite insensitive to it for 20 years. The sensitization in Case 4 was specific; in Case 5 it may have been specific, but the possibility of non-specific sensitization to bee venom (Foulkes, 1939; Bray, 1934; Oriel, 1936) should not be overlooked.

An explanation of sudden death occurring after wasp- or bee-stings often met with in medical literature (Dyke, 1941; Barber, 1941; Cummins, 1939) is that the sting has chanced to puncture a vein in the dermis, so that some of the venom enters the circulation direct instead of being fixed and destroyed by the skin. The cases detailed above lend no support to this notion. In Case 5 one cannot believe that the bees should have missed the veins a dozen times a year for 20 years and in the ensuing 9 months punctured them 11 times in succession. And in Cases 1, 2, and 3 it is hard to imagine that not one out of so many hundreds of stings should have struck a vein in the dermis. In fact, this theory of venepuncture is superfluous. A better explanation of such sudden deaths can be given in terms of idiosyncrasy, hypersensitiveness, allergy, or anaphylaxis. If the signs and symptoms observed in severe or fatal cases of bee-stings are compared with those recorded (Bray, 1934; Lamson, 1924) in severe or fatal cases of serum disease, as in the accompanying Table, the two are seen to be nearly identical, and death in each case can properly be set down to anaphylactic shock.

Severe Bee-stings	Severe Serum Disease
Restlessness, apprehension Unconsciousness	Restlessness, apprehension Vision completely lost Unconsciousness
General Symptoms	
Erythema, pallor Urticaria Giant urticaria Itching, local or general Numbness, tingling Generalized burning pain Sweating	Erythema, pallor Urticaria Large confluent wheals Itching, local or general Numbness, tingling Generalized sudden pain
Muscular System	
Uncontrollable twitching Muscular spasms Convulsions, rigor Transient paralyses of eye, pharynx, limbs Intense weakness	Twitching of face Spasms of arms and legs Severe convulsions, tonic and clonic Opisthotonos Dilatation of pupils
Heart and Lungs	
Anginal pain in chest Heart failure Heart beating after cessation of respiration Cyanosis Acute dyspnoea Cheyne-Stokes breathing Crowing respiration Respiratory failure	Pain in chest Heart failure, syncope Heart beating for 3 to 15 minutes after cessation of respiration Cyanosis Acute dyspnoea, choking cough Typical attack of asthma Respiratory failure
Digestive Tract	
Violent diarrhoea and vomiting Loss of sphincter control Inability to swallow	Violent diarrhoea and vomiting Loss of sphincter control

Summary

The frequency of bee-stings in Kenya Colony is noted. Three cases of multiple bee-stings with recovery and 2 fatal cases are recorded.

The suggestion that fatal cases occur when the sting penetrates a vein is discredited.

It is argued that death in fatal cases of bee-stings is due to anaphylactic shock, as it is in fatal cases of serum disease.

My thanks are gratefully offered to Drs. G. V. W. Anderson, J. A. Carman, P. J. Curtis, R. A. W. Proctor, and V. G. L. van Someren for much of the information given above.

INDIRECT RADIOTHERAPY*

BY

W. VIGNAL, M.D.Paris
Lieut.-Colonel, Fighting French Forces

Radiotherapy as ordinarily practised exerts a local destructive effect. Indirect radiotherapy produces good results by its effects on function, especially that of the sympathetic and glandular systems. Radiations act very differently on cells *in vitro* and *in vivo*. Their effects cannot be measured solely by the morphological changes which they produce; other less-known modifications have a great field of usefulness in treatment.

Cardiovascular Disorders

In *arterial hypertension*, which Vaquez showed to be due to excessive development of the suprarenal glands, irradiation of the suprarenal capsules has been widely practised since 1913. Generally speaking, in chronic constitutional hypertension with no evidence of nephritis or of any other assignable cause, irradiation does not reduce the blood pressure any more readily than do the simpler methods of rest and diet. On the other hand, it often greatly relieves the functional symptoms, such as headache, vertigo, spasm, and muscae volitantes. Similar results are obtainable with high-frequency current. Moreover, exacerbations of hypertension are quickly controlled by irradiation of the suprarenals, though the underlying condition is unaltered. The dosage is comparatively slight, and no change in the suprarenal tissues has been observed at necropsy. These apparently contradictory observations may be explained by Bard's differentiation of arterial hypertension into several varieties. Some of these he suggests are compensatory either for some known disorder like nephritis or for an unknown disturbance. To reverse the physiological changes, the cause, whatever it is, must be treated. On the other hand, hypertension due to a derangement of the mechanism controlling arterio-constriction is amenable to suprarenal irradiation.

Thrombo-arteritis obliterans falls into two classes: local, due to compression, embolism, or localized thrombosis; and general. Local forms may respond to various other kinds of treatment but never to radiotherapy; in the general group, cases which develop rapidly from infection and septicaemia do not respond to irradiation, but chronic and subacute cases

---

* Translation abridged for publication.

—for instance, in young or old persons or in diabetics—can be notably improved and sometimes clinically cured. The results depend on the stage at which the lesions are treated. The best time for treatment is naturally when the symptoms are still at their mildest and the vascular system can respond to irradiation of the sympathetic nervous system.

Thrombo-arteritis generally attacks a large artery and always sets up a reflex vasoconstriction of the collateral circulation. The aim of treatment is not to restore circulation in the artery, for this cannot yet be done; it is to suppress the vasoconstrictor reflex and so allow the collateral circulation to continue to supply blood to the limb. Accordingly, irradiation is applied to the suprarenal area—i.e., between D 10 and L 2; to the periaortic plexus, which surrounds the iliac arteries; and to Scarpa's triangles and the popliteal spaces ("*carrefours arteriels*"). The pain nearly always disappears, though on the night after the first or second treatment the symptoms are aggravated. When the pain is associated with gangrene, radiotherapy is only palliative. On the other hand, irradiation acts on the vasomotor symptoms almost at once. The patient often notices during the first treatment a feeling of heat, which can be felt by the hand; the limb can also be much more readily warmed in bed or by an external source of heat. The oscillometric index hardly ever varies to correspond, and the claudication is reduced but never entirely banished.

On *trophic disorders and gangrene,* irradiation has an undeniable but an unreliable effect. The least favourable indications are torpid wounds and chronic gangrene in old persons. The results have, of course, to be assessed with discrimination. In sphacelus and gangrene the pain due to the arteritis is relieved, and frequently the gangrenous process is arrested and a drainage channel is formed; sometimes the condition may even clear up. In other cases the local pain due to the gangrene persists in spite of a strong impression that the process has been stopped or slowed. The limb will then have to be amputated; but the patient's condition may be much improved, as the operation can be performed under better conditions, sparing a larger portion of the limb.

Arteritis in old patients, especially when the calcified arteries are visible in the radiograph, gives the least encouraging results. Juvenile arteritis is the most favourable indication. In *diabetic* patients the most important requirement is to reduce the blood sugar. The prognosis for *moist gangrene* is always very bad.

Irradiation of the sympathetic also produces several effects apart from the changes in the pathological condition. In *Raynaud's disease* it has little action by itself but reinforces the action of diathermy. When the cervical region is included it will often clear up vasomotor symptoms due to *trauma* in which disturbance of the sympathetic balance produces vasoconstriction. Possibly it might have an equally beneficial effect on *pathological vasodilatation,* as in erythromelalgia: its action is polyvalent, and it produces always the effect opposite to that of the pathological condition.

There exists in most *cardiac disorders* a functional element which is susceptible to irradiation. Several workers, including Pruche and Bienvenue, give a small exciting dose to an area of the cervico-dorsal spine at the level of the stellate ganglion. The results are a toning-up of the myocardium, reinforcement of the action of digitalis, and diminution of the tachycardia; but no definite conclusion can yet be drawn from the relatively small number of cases treated.

Dermatoses

Gouin and Bienvenue found that the irradiation of *primary warts* would clear up secondary warts at a considerable distance. They suggest that the rays excite the nerve endings of the skin to produce, by way of the afferent fibres of the vegetative system, sympathetic reflex actions which modify the lesion. This theory does not seem to apply to the particular instance of warts, but has been borne out by their results in other skin disorders. Since 1924 they have treated *Wilson's lichen planus* by superficial irradiation of the interscapular region, the rays being centred on D 4 for lesions of the upper and on D 10 for lesions of the lower limbs. They give only one application, and if it fails they do not try another for three weeks. The evening after the treatment the pruritus is often aggravated for two or three hours, but by the next morning it completely disappears; during the next three or four weeks the papules flake off and disappear. Pautrier of Strasbourg uses a method which he calls medullary radiotherapy: he employs thicker filtration, a higher kilovoltage, and a larger dosage, given in two parts at intervals of three days. Broadly speaking, Gouin and Bienvenue limit the action to the cutaneous afferent fibres, while Pautrier's aim is to irradiate the roots or medullary ganglia of the visceral sympathetic system. His method is perhaps better adapted to cases of longer standing.

In *supramalleolar erythrocyanosis* Gouin and Bienvenue use either spinal or axial irradiation. When the skin disorder is associated with others, such as dysmenorrhoea or acne, they irradiate the arterial *carrefours;* if the menstrual trouble is predominant, they begin by spinal irradiation and irradiate the *carrefours* three weeks afterwards. The duration of *chilblains* can be considerably shortened by irradiation of the *carrefours,* and they may be prevented from recurring. If they have ulcerated before cicatrizing they will secrete copiously. They clear up a fortnight after irradiation.

Acrocyanosis is treated by irradiation of the *carrefours,* or, if this does not succeed, of the interscapular region or the lumbar curve as the case may require. In long-standing cases the suprarenal area should also be irradiated. Cure is hardly ever quite complete. In *eczema with lichen formation* the methods both of Gouin and of Pautrier have succeeded brilliantly. During the war of 1914-18 Delherm obtained remarkable results in *causalgia* by irradiating the various spinal sympathetic branches and the vascular *carrefours. Schulze's acroparaesthesia* has also been cured or much improved by the same method; and it will often mitigate *pain in amputation stumps.*

In *diabetes mellitus* indirect irradiation brings about two interesting effects. Desplats of Lille reported that it reduced the glycosuria; and in some cases irradiation is followed by a sudden rise in excreted sugar followed by a gradual fall which lasts a long time. In severe diabetes with emaciation, on the other hand, irradiation, when it has any effect at all, makes matters worse. Irradiation of the pituitary gland will often render insulin-resistant patients sensitive. Obviously it acts on the sugar-regulating function of the anterior lobe, but in order to be effective the hormone of this lobe must have adrenaline associated with it.

In *menstrual troubles* not due to any lesion or anatomical abnormality, irradiation of the *carrefours* gives interesting results. The disorder of ovarian function responsible for these troubles often coincides with facial acne, pruritus, or eczema of the genital region. Desplats, irradiating the suprarenal area instead of the lumbar curve, obtained good results alike in this class of disorder and in those associated with the physiological or surgical *menopause.* Usually a single treatment is sufficient; if it is not, a second and sometimes a third are given, at intervals of eight days.

Asthma has been treated by irradiating various portals of entry, including the thorax, the thorax and spleen, the pituitary, the pancreatic region, and the bulb. The exponents of these different techniques adduce their successes to confirm a variety of aetiological theories; the benefit is probably due to a non-specific protein shock.

In *Graves's disease* associated with sympatheticotonia, an inverted oculo-cardiac reflex, and a basal metabolism only slightly above normal or even a little below it, neither irradiation of the thyroid nor surgery gives any relief; the only effective treatment is irradiation of the suprarenal area.

Mechanism of Action

As the very small dosage produces no anatomical change it must modify function. The glandular secretions have been shown to be increased or reduced by it—a somewhat disturbing observation, for histologists (except for the doubtful results of R. Isaacs) have never yet been able to demonstrate that *x* rays stimulate cellular metabolism. On the other hand, radiations are known to modify, *in vivo* and *in vitro,* the fluid media of the body. Certain organic compounds—e.g., cholesterin, the fats, and amidin—are split up by hydrolysis; and the viscosity of the colloids is increased, according to dosage, up to the point of gelation. Richard Seyderhelm, by injecting previously withdrawn blood, could prevent or cure the anaemia induced in an animal by the injection of saponin. It seems permissible to assume that these chemical changes, and perhaps also others as yet unknown, affect the glandular system without producing any appreciable anatomical alteration. They naturally vary according to the nature and degree of the disorder.

Through all the portals of entry employed the rays have access to the sympathetic nervous system. Radiotherapy therefore can modify the function of the sympathetic, and also of its perivascular plexuses, in various ways according to the dosage and the degree of excitability of the nerves. Gouin and Bienvenue produced by irradiation of the sympathetic the same reactions in the blood and the same clinical and therapeutic phenomena as Leriche produced by surgery. Moreover, besides the endocrine glands, which secrete their products into the blood, P. Masson has demonstrated the existence of endocrine tissues which secrete directly into the nerves. These two actions, humoral and nervous, proceed together. For instance, adrenaline acts by exciting the sympathetic nerves. Comparative anatomy and embryology show the close association of chromaffin with the sympathetic, and experimental physiology shows the close interaction of certain hormonal influences with corresponding neural factors—"sympathetico-glandular synergy." It is therefore easily conceivable that radiotherapy applied to the sympathetic and glandular systems may excite modifications which produce the beneficial effects that have been noted. As yet no one knows why or how it restores a disturbed balance by acting on that phase of the reciprocal vegetative function which happens to be impaired. This and many other difficult questions remain to be answered, and the answers will be as interesting as they are valuable.

TREATMENT OF PHOSPHORUS BURNS

BY

A. THELWALL JONES, M.D.

A notable increase in the incidence of phosphorus burns must be expected under war conditions, and the article by E. W. Godding and H. E. F. Notton in the *Journal* of April 4 (p. 433) is therefore timely and useful. There are several points in this article which deserve further comment. It should be stated that the "official treatment" which they critically examine has been based on the practice gradually established through long clinical experience within the chemical industry and is the result of careful observation over many cases. These authors are under a misapprehension on one minor issue, as they assume that the copper sulphate treatment is designed chemically and completely to destroy the phosphorus particles left in the affected area after the preliminary washing. This is not the primary object, which is rather to destroy minute particles and to make obvious, by blackening, the larger pieces so that they can be removed mechanically. There is no present clinical evidence that the concentrations, both of alkali and of copper sulphate, suggested "officially" are inadequate, and indeed the extant case histories indicate that they are well chosen. Godding and Notton have done well, however, to stress that the alkaline treatment must be thorough, and the importance of this feature is borne out by my practical experience. A novel problem associated with present conditions is the satisfactory treatment of phosphorus burns under field or Service conditions. Here the practice found good enough in industry would often be difficult to apply with the requisite speed, and a satisfactory field dressing would be a valuable contribution to the casualty services. The powders suggested by Godding and Notton may prove of value in this connexion, and should certainly be given a thorough trial on human cases; it may be possible to get the requisite experience industrially. One further caution is necessary: Godding and Notton experimented with material from S.I.P. (self-igniting phosphorus) grenades, and this is not strictly comparable to the phosphorus as encountered in industry, though the effects may reasonably be assumed to be similar. The following notes on the treatment of phosphorus burns may be of interest:

Characteristics of the Burns

Burns caused by phosphorus have long been recognized as particularly severe and troublesome lesions. They have these characteristics: (*a*) the initial pain is severe; (*b*) a greyish area is produced almost immediately at the site of the lesion, and blistering is rare; (*c*) sepsis is particularly apt to ensue; (*d*) healing is prolonged, and the resulting scar is often thin and atrophic. During the past ten years I have had the opportunity of studying burns arising from a variety of chemical irritants and corrosives. Generally, the severity of burns is proportionate to the chemical nature of the causative agent, and may be placed in the following order: (1) hydrofluoric acid, (2) phosphorus, (3) sodium sulphide, (4) caustic soda, (5) sulphuric and other acids.

Method of Treatment

The essential factor in the treatment of all chemical burns is the immediate flooding of the area affected with water or sodium bicarbonate solution. It is necessary to organize an adequate first-aid service for this purpose. Buckets of water, running water, eye-wash bottles, and, in special cases, baths must be instantly available. Experience has indicated that immediate flooding with water and *prolonged soaking* in *warm* sodium bicarbonate solution is the essential feature in treatment.

Altogether 65 cases of burns caused by phosphorus have been observed, the records of which are set out in the accompanying Tables. (In every case the time taken to heal is recorded as a period which elapsed before the employee was able to return to normal work without *any* dressings.) Several methods

Cases treated with Sodium Bicarbonate, Copper Sulphate, and Tannic Acid

Age	Date of Burn	No. of Burns	Area Affected	Degree	Total Size (sq. in.)	Days Absent from Work	Days taken to Heal	Comments
40	18/1/37	2	Two fingers	3	1¼	Nil	32	Painful
21	3/2/37	1	Hand	2	¼	24	5	,,

of treatment have been tried, and as a result of the experience gained the following procedure is advised:

(1) Immediately flood the affected area with water.

(2) Thoroughly flood and wash with warm sodium bicarbonate solution (roughly two tablespoonfuls to a pint of water). Pick off with forceps any obvious particles of phosphorus disclosed by examination in the dark.

(3) Swab the affected area with 1% solution of copper sulphate and make a further exploration for phosphorus particles so revealed. Soak the affected area (immerse if possible) in warm sodium bicarbonate solution for a prolonged period. The duration of this soaking depends upon the size and depth of the burn—i.e., small burns 1/2 hour, large burns 1 to 2 hours.

(4) Dress daily with acriflavine emulsion 1/1000. Burns near the eyes are best treated by a mask of lint soaked in sodium bicarbonate solution renewed four-hourly.

(5) Immediately healing begins (7 to 10 days) boroseptic ointment (P. D. & Co.) provides a very satisfactory dressing, and its use can be continued until the scar produced is sound.

Tannic acid and other coagulants do not give satisfactory results, as is also the case in the treatment of all chemical burns. Acriflavine emulsion has the disadvantage that in some individuals local and generalized skin eruptions may be produced. A daily inspection will detect such lesions at an early stage, when boroseptic ointment should be substituted.

As a result of such treatment results are obtained which compare favourably with a similar series of burns caused by caustic soda and sulphuric acid. Healing is slower and scars are thinner in burns caused by phosphorus.

RELATION OF PYOGENIC SKIN INFECTIONS TO THE SKIN-CARRIER RATE

BY

N. H. MARTIN, B.M., M.R.C.P., F.I.C.

*Major, R.A.M.C.**

Bacteriological investigations have demonstrated that a fraction of the presumed healthy population carry potentially pathogenic staphylococci on their wrists. The actual proportion of carriers varies from 5% found by Nimmo-Smith (1941), examining R.A.M.C. personnel, to 19.5% found by Gillespie, Devenish, and Cowan (1939), examining students. Devenish and Miles (1939) appeared to show that a previous history of pyogenic skin infection was not given by a significantly higher percentage of skin carriers than normal.

The Present Investigation

The object of the investigation was to discover whether or not the carrier rate varies with the part of the body sampled, and if there was a significantly higher carrier rate in people suffering from pyogenic skin infections as judged by multiple swabbing. The series investigated consists of group A, 140 patients suffering from pyogenic infections of the face or neck, and group B, 100 individuals having no demonstrable pyogenic lesions. An effort was made at first to ascertain whether or not individuals of group B had at any time suffered from pyogenic skin infections. This was abandoned because it was clear that they were not equally reliable as witnesses. So far as the inquiry went there seemed to be no evidence of a significantly higher carrier rate among those giving a previous history of skin infection.

Technique.—Three swabs were taken from each person. The first swab was from the upper lip in group B and from the upper lip where possible in group A, but in every instance at least one inch from the nearest demonstrable lesion. The second swab was taken from the right wrist in right-handed people and from the left wrist in left-handed people. The third swab was taken from the chest in the midline opposite the second rib. At each site an area of 2 sq. cm. was sampled with a broth-impregnated swab which was stroked over that area 30 times in 30 seconds. The swabs were immediately plated out on blood agar and on gentian-violet agar at 37° C. for 24 hours. The plates were then examined, and selected colonies of staphylococci were subcultured and tested for their ability to form coagulase. At the same time their ability to form pigment was noted. The coagulase test was chosen as a basis for assessing pathogenicity; and it was observed that 5 out of 151 strains isolated from group A failed to produce any pigment though they were coagulase-positive. McFarlan (1938) showed that a number of non-pathogenic strains of the staphylococcus would ferment mannitol, and this test was not carried out. The plates containing gentian violet were used for the isolation of streptococci.

Discussion

The results are shown in tabular form. There is in the series under review a significant increase in the "complete carriers" of potentially pathogenic staphylococci in group A. Though this may be, and probably is, a transient phenomenon, the carrier area appears to be extensive. A comparison of the carrier rate for the face, wrist, and chest in each group shows that in group B it varies, being highest, as might be expected, on the face. In group A the variation though present is not so marked, the difference between face-carrier rate and chest-carrier rate being 13.2%, compared with 24% in group B.

There appears to be a significant rise in the incidence of β-haemolytic streptococci on the face in group A, but not elsewhere. Here again recovery of the organism varies with the area sampled. The figures seem to demonstrate that the presence of a localized skin lesion produces a wide-spread increase in pathogens on the normal skin. If this be so it must materially alter our conception of the results to be expected from localized forms of treatment for pyogenic skin infections.

Table of Skin Carriers

	Carrying Coag. + Staphs.		Carrying β-haemolytic Streps.	
	Group A	Group B	Group A	Group B
Face only ..	13·1%	15·0%	6·5%	3·0%
Wrist only ..	8·0%	3·0%	1·4%	1·0%
Chest only ..	3·6%	1·0%	Nil	Nil
Face and chest ..	5·1%	4·0%	Nil	Nil
Face and wrist ..	8·0%	12·0%	0·7%	1·0%
Chest and wrist ..	4·3%	2·0%	Nil	Nil
Face, wrist, and chest	30·7%	7·0%	1·4%	1·0%
Total face ..	56·9%	38·0%	8·6%	5·0%
Total wrist ..	51·0%	24·0%	3·5%	3·0%
Total chest ..	43·7%	14·0%	1·4%	1·0%

My thanks are due to Col. R. Rees for permission to publish this paper.

Medical Memoranda

A New Diagnostic Sign in Sciatica

Sciatica in form of neuritis or neuralgia presents a problem of grave importance on account of its frequency and chronicity. The loss of working days due to the condition is considerable.

Very often sciatica reveals itself only as a pain along the course of the sciatic nerve, without objective symptoms, such as alterations in knee- or Achilles jerks, trophic changes, etc. The surest indication of the existence and intensity of sciatica is the sign of Lasègue. This consists in an increase of pain when an attempt is made to extend the leg with the thigh flexed. The intensity may be measured by the angle at which the pain arises. Putti terms this L+++ if the pain is felt before the leg reaches 45 degrees with the axis of the thigh, L++ at 45 to 90 degrees, and L+ at 90 degrees and complete extension. The Lasègue sign is the result of stretching of the affected nerve. Several other signs depend on the same cause—i.e., the sign of Neri (flexion of the head, producing sciatic pain), and that of Goldthwait (flexing the thigh to a point of tolerance with the knee flexed, and then forced extension of the knee). To these we must add the contralateral sign of Lasègue, described by Montard-Martin and Parturier, and by Bechterew.

Lasègue's sign is very reliable, but in my opinion is too often positive. There are two reasons for this. First, as Bragard has shown, often purely muscular changes of the thigh in form of thickenings (*Muskelhaerten*) give a positive Lasègue sign (*Pseudolasègue*) in the absence of nerve involvement; secondly, certain individuals, for purposes of malingering, try to deceive the physician by false statements—many of them being acquainted with the Lasègue sign.

In many years' experience I have always controlled the Lasègue sign by the sign of Bragard, which I regard as of great diagnostic value. It consists in considerable increase of pain when a sudden dorsal flexion of the ankle is performed at the point where pain begins. Personally I employ the classical sign of Bragard plus this modification: at the point where pain disappears on lowering the leg, a sudden dorsiflexion of the ankle produces pain in the formerly painless leg.

My new phenomenon is as follows. The leg, flexed at the hip-joint and extended at the knee, with the foot in dorsiflexion, is slowly raised. In the case of sciatica a point is reached at which pain arises (first stage); a sudden extension of the foot now causes the pain to disappear instantly (second stage). This is a reversed Bragard sign.

I hope the new sign here described will be of help to physicians not only for the diagnosis of sciatica but also for revealing cases of malingering.

Reviews

MEDICINE AND SOCIOLOGY

Society and Medical Progress. By Bernhard J Stern. (Pp 264 $3 00 or 18s 6d) Princeton Princeton University Press; London: Oxford University Press 1942.

Mr. Bernhard Stern, although a social scientist working outside the medical profession, proves in his *Society and Medical Progress* that he has paid close attention to the interactions between medicine and sociology. His first chapter on the slow emancipation of medicine from magic and its congeners does, however, give rather too depressing a view of that delay. Thus an epoch which produced Heberden's *Commentaries* can hardly have lacked clinical observation and scientific reasoning so much as is here suggested: on the other hand the reasons for the decline of medicine between Galen and the Renaissance are clearly stated in the quotation from Vesalius. As the author points out, medicine cannot develop and never has developed in isolation, for its progress is circumscribed by that of ancillary sciences and by the environment of the age. Urbanization has introduced new problems, as has the increasing proportion of elderly people. "Grave challenges are inherent in the new situation which medical science has helped to produce by its increasing efficacy. Medicine has not been able to provide economic security for the aged whose lives it has prolonged; that is not its province; but as he goes on to say, it has alleviated the mental suffering of populations in other ways than by the control of epidemics and the lowering of death and disability rates. One striking example is the new knowledge of nutrition, which is enabling this country to stand up to the strain of war to an unexpected degree. Yet as a rule the humanitarianism of the medical man has been mainly directed towards individuals; he has often ignored the larger social implications of his work. That, however, is tending to alter in the face of the present dangers to civilization.

The book closes with an interesting analysis of the factors that offer resistance to medical change; some internal, others external to the profession. Thus medical education has not really made up its mind whether it wishes to develop specialists or students whose training will enable them to develop competence to evaluate and use new methods as they arise. Obviously, we might urge that both are needed. Of ancient internal causes of delayed progress none was stronger than the contempt for the use of the hands, as Allbutt so vigorously insisted. More permanent causes are the reliance on authority and the dislike, by no means confined to medicine, of new ideas which challenge that authority. The external causes are antiscientific, romantic approaches to life and thought, which are not isolated phenomena but reflect the temper of intellectual life prevailing at the time. This in the last analysis he regards as related to the social and economic developments of the day.

NEURO-ANATOMY

Neuroanatomy By Fred A Mettler, M D, Ph D (Pp 476, illustrated 37s. 6d.) London· Henry Kimpton 1942

This is a superbly illustrated volume, which Prof. Mettler states "has been written to meet the needs of the medical student beginning instruction in neuro-anatomy and to prepare him for the demands which will later be laid upon him in his clinical training." The text is divided into two parts: (1) dealing with the topography and morphology of the central nervous system; (2) the microscopic anatomy of the nervous system. Although the author declares that no pretence of originality is made for any of the material presented, there is much which will be new to readers who have not made a special study of particular sections of the subject, such as that on the diencephalon and the structures related to it. This section is chiefly based upon data from Papez and Aronson, and is illustrated by schemata redrawn from these authors' work on the diencephalon of *Macaca mulatta*.

An enormous amount of material appears to have been used in the production of *Neuroanatomy*, as is indicated by the literature cited in a very full list of selected references. The outstanding feature of this work is, however, the production and illustration of a large number of specially planned dissections and of serial microscopical sections prepared by the Weigert and Nissl methods. Illustrations of the latter have been placed for comparison side by side, and all are fully and clearly labelled. From the standpoint of the medical student beginning the study of neuro-anatomy certain comments seem necessary. (1) There appears to be some danger of confusion arising from the great wealth of minutely described topographical details, and one would like to find further guidance in the way of introductory notes indicating the more important facts and principles, a knowledge of which is essential for medical practice. (2) A short introductory account would be welcome of particular organs or systems, such as the hypophysis or cerebellum, indicating their main functions, with reference to, and in explanation of, their anatomical relations. (3) Some brief allusions to the developmental history and comparative anatomy of particular organs and parts would enhance the general interest of the subject and give a scientific explanation of certain anatomical facts and peculiarities of the mammalian brain, such as the evolution of the corpus callosum, the nature of the septum pellucidum and its cavity, or the course of the spinal accessory nerves.

Neuroanatomy may be regarded as an authoritative work, which is beautifully illustrated and includes, in one volume, a clear description of the subject as a whole, and also embodies an account of important recent contributions to the anatomy of particular regions of the central nervous system that will be of great value to nerve specialists.

CARE OF THE PREMATURE INFANT

The Premature Infant: Its Medical and Nursing Care. By Julius H. Hess, M.D., and Evelyn C. Lundeen, R.N. (Pp. 309; illustrated. 21s.) Philadelphia, Montreal, London: J. B Lippincott. 1942.

A book on *The Premature Infant* by Prof. Julius H. Hess is sure of a welcome, and in this new volume, with its subtitle "Its Medical and Nursing Care," he has been assisted by Miss Evelyn C. Lundeen, who is the supervisor of the special department of the Sarah Morris Hospital, Chicago, where so much valuable work on the premature baby has been done. It is over 20 years since Dr. Hess first published his well-known work on this subject, and the present volume, containing as it does a certain amount of material from that book, may be regarded as a sort of sequel in which the practical implications of his earlier teaching have been fully worked out. Thus details are given of all the procedures recommended, and chapters on incubators, on home care, and on feeding, for example, are full of well-tried and useful practicalities. Something might have been included about intracranial disturbances other than haemorrhage, nor is there any mention of the use of thyroid gland or oestrogen as a possible metabolic stimulant in the early days of life. These are, however, minor matters in a large subject, and all having the care of premature infants will find much of value to study in this book. Properly mastered, the methods advocated should go far to reduce the neonatal mortality as effectively in Great Britain as it has been reduced in Chicago.

SCIENCE OF PERSONALITY

Foundations for a Science of Personality. By Andras Angyal, M.D., Ph.D. (Pp 398, $2.25 or 13s 6d.) New York: The Commonwealth Fund; London: Oxford University Press 1941.

This dissertation on personality postulates that the subject must be studied as a whole and not simply as an aggregation of parts. This does away with the antithesis of body and mind and formulates them as different aspects of study within the whole. Personality is essentially dynamic and not static, and the chief trends within it which react and interact are the tendency to greater self-determination (autonomy) and that towards conformity with the dictates of superindividual wholes, such as society and culture (homonomy). The first tends to impose the intrinsic determination of the individual upon a widening realm of events (aggression); the second tends to fit the individual into schemes of culture, religion, etc. (submission). Obviously in man the specific channels for expression of personality are extremely diverse and more or less defy classification.

Dr. Angyal discusses the integration of the personality and disturbances of this and attempts to define the systems which make up the personality. A complete view of the personality, however, can only be obtained if the time dimension (the biography) is also taken into account. In handling segmental data (physiology, psychology, anthropology, etc.) each of these should be related to the whole and not to each other (e.g., psychology to physiology). The subject is dealt with from the philosophic point of view and so may not be very easy reading for many medical men, but it is important in the understanding of the main object of medical study—the human being.

Notes on Books

Ornithologists of the United States Army Medical Corps, by Colonel EDGAR ERSKINE HUME of the U.S. Army Medical Corps is published at Baltimore by the Johns Hopkins Press, price $5. It is not easy to understand the purpose of this book, which can have little appeal to British medical readers and bird lovers. It is a record of the lives of thirty-six U.S. Army surgeons, each of whom is the subject of a chapter containing references to ornithological contributions. Most of the biographies deal with the stirring times when the U.S. Army was on active service winning the great west from hostile Indians, and are interesting in that respect. The growth of the American Army Medical Department from a handful of officers in the 'fifties to the huge organization it now is can be traced throughout these lives. There is, however, not much information of value to those of us who are keen on birds, and, indeed, there is little that requires to be said, for the immortal pioneer work of Audubon, Wilson, and Nuttall has placed American ornithology on a high plane and has been followed by a host of scientists who have done work of distinction in recording accurate observations on birds. The volume is well illustrated with photographs of the doctors and the forts where they were stationed. Most of the birds described are not indigenous to this country. Colonel Hume, who is a military medical historian, says in his introduction that he "cannot himself claim knowledge of ornithology, but only admiration from a respectful distance." American medical officers will nevertheless find this book about their predecessors very readable.

Tropical and Sub-Tropical Diseases, by Dr. C. H. BARBER, is published as one of the Oxford War Manuals at 5s. by the Oxford University Press. The stated aim of this pocket compendium is to serve the needs of medical men in the Forces over-seas. Its scope is wide and 60 diseases and morbid conditions are given in the table of contents. The space allotted to each varies from 20 pages (malaria) to 8½ lines (myiasis). There are some strange omissions. Nothing is said of *Cordylobia* infestation, a real pest in the last war and already troublesome in this, or of the dosage and course of pentavalent compounds of antimony in kala-azar, yet room is found for accounts of goundon and ainhum, neither of which is likely to give rise to any urgent problem. Possibly due to hasty compilation, there are some muddled and confusing statements. Thus on p. 25 the oddly named species "*Culex Fatig.*" and "*Culex P.*" are shown as genera, and on p. 134 it is stated that the "diurnal periodicity" of microfilariae coincides with that of "the chief insect vector . . . namely, the *Stegomyia mosquito*, or Culex fatigans (*Aëdes variegatus*). In the Pacific Islands, however, this periodicity does not obtain." This is a hard saying. The lack of system in writing zoological names, as in the foregoing extracts, is general throughout the book; sometimes the author follows the directions of the International Rules, sometimes not, and the resulting patchwork is most unpleasing to the trained eye. In view of the expressed object of the compendium, medical officers of the Army would be well advised to stick to the official "Memoranda on Medical Diseases," etc., until something better than this Oxford War Manual comes along.

The public schools of this country are going through difficult times, and the relative advantages and disadvantages of day schools and boarding schools are under keen discussion in the Press. What will come of it all remains to be seen, but meanwhile the 53rd annual issue of the *Public and Preparatory Schools Yearbook* has been published by H. F. W. Deane and Sons at 10s. 6d., and fulfils its useful task of supplying information to the parents of to-day. No fewer than 30 public schools and 158 preparatory schools for boys have had to move their quarters owing to the war. Temporary addresses, with cross-references to the normal home of each school, are given and brief details of altered arrangements. The schools listed in this yearbook are those represented at the Headmasters' Conference or belonging to the Association of Preparatory Schools. It also contains particulars about the universities and some guidance on careers.

MECHANICS OF THE CIRCULATION

Those who begin to study the circulation often find themselves in difficulties about its mechanics, and, to surmount these, many attempts have been made to study it by means of models. Most teaching schools have some sort of a model illustrating the factors concerned in the maintenance of the arterial blood pressure—i.e., the output of the heart together with the peripheral resistance and elasticity of the vessels—but no one has yet produced a model that demonstrates satisfactorily all the changes possible in the living animal. The latest attempts are those of L. Bayliss,[1] and of Price, Sloan, and La Rochelle.[2] The latter, indeed, have from a study of their model gone so far as to say that the concept of a disparity between blood volume and vascular capacity does not bear analysis, and criticize on this account even the possibility that shock may be due to such disparity, forgetful, apparently, that a model can be made to prove anything. As a guide to model makers it is, then, not out of place to indicate what is required.

First, a pump is necessary which will not only vary its rate, stroke, and force, but will fill in the first third of diastole in virtue of the venous pressure, for without this it is not possible to illustrate properly the law of the heart and the full effects of rate on output. Without this facility the output per beat is reduced whenever the rate is increased, because the filling is reduced. Such a pump was not used by those referred to. But that is not to say, as pointed out by Starling, that the output of the heart per minute is necessarily a function of the rate, for if the venous pressure is low the heart may need all its diastole to fill. In some circumstances, such as after very severe haemorrhage, the filling may be so slow that slowing of the heart may actually cause a slight rise of arterial pressure. It is also very difficult to construct a pump which will automatically vary its force according to the amount of blood in the heart at the beginning of systole so that there is an increased output per beat in approximately the same systolic time as a smaller output. In these days a simple model is available in the form of a stirrup pump made to discharge into the pail, but it does not show the infinite variation of the circulation.

The effects of cardiac failure and reduced cardiac output are easily shown on a model or on an animal by increasing the pericardial pressure or by stimulating the peripheral end of the vagus. There is a rise of venous pressure, which in the model is accompanied by a fall of arterial pressure, but in the animal or man, in whom such failure is a common feature of cardiac disease, the arterial pressure does not fall until all the vasomotor compensation has been called into use. In man we see the engorged veins of chronic venous congestion standing out in a pallid skin. It is possible, too, that a high venous pressure may eventually interfere with the emptying of the coronary sinus and cardiac nutrition. Increased cardiac efficiency has the opposite effects both in the model and in the animal, but for reasons given later this is difficult to demonstrate unless the heart has first been rendered inefficient.

In the majority of models, simple or elaborate, the effects of simple changes in the peripheral resistance are also easy to show. A decrease results in a fall of arterial pressure accompanied by a simultaneous rise in venous pressure that is the same as in cardiac failure, but with the difference that all degrees cause the fall of arterial pressure and the rise of venous pressure coincides with it. A fall of resistance is brought about by a minute dose of acetylcholine, a rise by clamping the aorta. Most of the other procedures and drugs which affect the peripheral resistance complicate the issue by affecting the capacity of the circulation. This variable capacity of the circulation was unknown until it was demonstrated by Dale with Richards and Laidlaw,[3] [4] and Krogh[5] demonstrated that capillaries, normally closed, might open and soak up the blood like a sponge, greatly diminishing its return to the heart. But as the capillaries contribute to the peripheral resistance it is necessary to construct a model which will incorporate these features. An increased capacity is produced by histamine, by amyl nitrite, after asphyxia, and, normally, after severe exercise. There is not only a fall of arterial pressure but also a fall of venous pressure, which may, however, be preceded by a rise due to the fall of peripheral resistance if the capacity does not increase so rapidly as to mask it. As the return of blood to the heart is reduced vasomotor compensation ensues, and there is a rapid recovery of the peripheral resistance (due to arterial and arteriolar constriction); the arterial pressure recovers appreciably through the venous does not. The arterial constriction shows itself in a rise in the velocity of the pulse rate for a given internal pressure (McDowall).[6] This cannot easily be imitated by any model. A similar return of the arterial but not the venous pressure is also seen after slight haemorrhage. The significance of any given changes in the intact circulation can be interpreted only when they are compared with the results from the study of blood flow, limb volume, and perfusion resistance, and in this the paper of Dale and Richards[3] is a model worth studying. Wiggers has also made extensive studies of this problem from the shape of the pressure pulses obtained by means of the Frank's capsule.

The administration of amyl nitrite gives an interesting series of changes which may be analysed thus. First, accompanying the fall of arterial pressure is a large fall of venous pressure due to increased capacity, preceded, maybe, by a short-lived rise due to reduced peripheral resistance; but at the stage when the height of arterial pressure depends largely on the arterial compensations there is a rise of venous pressure only. When the increased capacity of the circulation is caused by a generalized loss of vasomotor control there is a fall of arterial and venous pressures, but the arterial compensation is absent. This state is produced experimentally by sections of the spinal cord in the neck which cuts off the sympathetic supply to the body, and is probably present in the ordinary faint and in the neurogenic variety of shock. Recently, McDowall[7] has pointed out that the fall of peripheral resistance may be a major factor in those cases of shock which fail to respond to the transfusion of blood or plasma. Moreover, in the intact animal the pulmonary circulation may affect the greater circulation. Thus intense pulmonary constriction may cause a delayed rise of venous pressure from failure of the right heart, as with histamine, in which case it masks the early effects of increased capacity. Similarly, sudden rapid constriction of pulmonary vessels may cause falls in arterial pressure. The reverse may also occur. Respiration lso affects the resistance and capacity of the pulmonary essels. The resistance is increased and the lung capacity decreased by expiration, while the reverse occurs in inpiration. Their effects on the arterial and venous pressures lo not coincide exactly with the pulmonary change, but are lightly delayed. It has to be remembered, too, that usually hanges in the heart rate are accompanied by changes in he vessels. Thus in a faint vessels are dilated (except the kin) while the heart is slowed; the reverse occurs in the xcitement and early exercise. Drugs, also, often produce ffects on both heart and vessels—e.g., adrenaline and ligitalis. Further, there is a vast number of venous and arterial reflexes by which rises and falls in pressure affect oth the heart and vessels. Models cannot imitate these, or all are not completely understood. Finally, we must onsider other unknown factors in the circulation, such as he psychological. At the moment, one of the most puzzling roblems is that the heart rate so commonly falls in donors vhen blood is given, when all past experiences, both xperimental and clinical, would lead us to expect that it would rise. Thus we see how inadequate models of the irculation are liable to be; they can be of value primarily to illustrate a fact already derived from a study of the experimental animal.

THE SCIENTIFIC LIFE

It is possible to hold two wholly different views of the qualities and circumstances favourable to success in scientific research. More than 300 years ago Francis Bacon formulated a grand, or grandiose, scheme which was to reduce scientific discovery to laborious but unimaginative team-work. Bacon's plan received the support of a few *philosophers* who were not themselves scientific workers, but, with the doubtful exception of Robert Boyle, none of the great researchers of his age had much use for Bacon's plan, and Harvey spoke of it with gentle sarcasm. That continued to be the attitude of most researchers down to our own time. They did not hold that discovery was a mere matter of luck, but they did think, with Pasteur, that chance helped people whose minds were ready to be helped and that fine original work in science depended on the freedom of the human spirit, that the utilitarian aspect of any proposed investigation was about the last which should be *given weight in choosing one's subject*. This attitude was never approved by practical men, and recently some writers who have to their credit considerable achievements in pure scientific research, and therefore cannot be reproached with ignorance of the way in which discoveries are made, have explicitly or implicitly condemned it. One of them reviewed Prof. G. H. Hardy's *A Mathematician's Apology* with almost theological acrimony. This was not surprising, because Prof. Hardy had explicitly maintained that the useful parts of mathematics were rather dull and the "real" mathematics of "real" mathematicians almost wholly useless, and *actually said that if a mathematician* or a chemist or even a physiologist "were to tell me that the driving force in his work had been the desire to benefit humanity, then I should not believe him (nor should I think the better of him if I did)."

The neo-Baconians have naturally a very different plan from that of Bacon, but are equally insistent upon fruits and equally scornful of what seem to them useless or unprofitable researches. Dr. John R. Baker in *The Scientific Life*[1] may not enrage the neo-Baconians quite so much as Prof. Hardy—he is not sure that mathematics and logic belong to science—but he will annoy them a good deal. He is satisfied that the statements "Science is a product of human demands" and "Science has evolved from crafts and industry" are simply untrue, that scientific research can no more be planned or organized than the writing of symphonies or poems, and that amateurs—*real* amateurs of science—are the salt of the earth. A *via media* is possible, indeed suggested by Dr. Baker. It is this. The neo-Baconians are not really talking about science at all in the sense that Harvey or Newton would have given to the word, but technology, and technology can be planned and organized. The neo-Baconians have no difficulty in showing that technology, or applied science, has not been well planned in this country; but Dr. Baker's contention is that pure science—namely, scientific work done because the worker either loved his work or was driven to it by a daemon—cannot be organized or planned at all, and that without such pure science technology must eventually perish. He evidently thinks that a remark made by the Soviet Ambassador to the British Association on September 27, 1941—"We in the Soviet Union never believed in pure science"—was not wise but foolish. Probably the neo-Baconians might retort (1) that nothing they can do will stop those with a daemonic urge to pure research; (2) that there is a sufficient capital of pure scientific knowledge still unapplied to occupy a great many more able second-rate people in technology than are at present employed. But totalitarianism has made great strides in this generation. One might add to Dr. Baker's numerous examples of pure researchers Hermann von Helmholtz. He was educated for the medical profession at the expense of the State; almost his first and one of his fundamental contributions to science was a memoir on mathematical physics (a subject not included in his university training and studied by him in his spare time because it interested him). The Prussian Government of almost a century ago was influenced by the judgment of real scientists and allowed Helmholtz to pursue an academic career to the glory of pure science and, in due course, technology. One may doubt whether the military authorities of either Potsdam or Moscow in 1940 would have learned with satisfaction that an assistant surgeon to the regiment of Hussars spent a great deal of time perusing the works of mathematicians. That, however, brings us to a last point to be had in mind when we try to judge impartially the merits of the current controversy. We should not forget that the authors whom Dr. Baker flagellates were writing under the shadow or in the presence of war and disaster when technology is of more *immediate* importance than science (to the ordinary politicians, of course, science and technology are synonyms, but science is thought to be a more flattering term). Something must be allowed for emotional stress; zeal and arrogance are not easy to distinguish. Very few of those who survive the war will look back with complaisance to all they said or wrote during its currency.

THE WERNICKE SYNDROME AND VITAMIN B_1 DEFICIENCY

Wernicke in 1881 described a syndrome characterized by ophthalmoplegia, clouding of consciousness, and ataxia, resulting from acute haemorrhagic polioencephalitis superior. The lesions are confined to the periventricular grey matter of the brain, which shows small foci of degeneration and varicose deformities of the blood vessels. Recently the disease has been attributed to a conditioned deficiency of vitamin B_1, as the majority of the cases diagnosed were the result of alcoholism, and most of the symptoms cleared up promptly on treatment with aneurin.

The syndrome may be associated with a combination of several nutritional deficiencies. However, an interesting confirmation of the view that aneurin deficiency is the principal causative factor of the disease comes from the observation of Wortis *et al.*[1] that patients with the Wernicke syndrome were unable to metabolize pyruvic acid normally. They showed a high fasting level of blood pyruvate, the figures being 1.44–3.63 mg. per 100 c.cm., as compared with 0.77–1.7 mg. per 100 c.cm. for normal subjects. When these patients were loaded with glucose an increase of their blood pyruvate occurred which lasted 4 to 5 hours, whereas healthy subjects under the same treatment showed only a transitory rise. After aneurin therapy the fasting level of blood pyruvate came down rapidly to normal, but the response to glucose loading became normal only after prolonged treatment. These experiments provide an interesting example of the use of a carbohydrate tolerance test for detecting vitamin B_1 deficiency, a possibility first suggested by Harris and co-workers at Cambridge.[2]

---

[1] London: George Allen and Unwin, Ltd. (7s. 6d.)

The Wernicke syndrome has a perfect analogy in the so-called Chastek paralysis of silver foxes which occurs as a result of feeding large quantities of raw fish. The disease is also characterized by anorexia, weakness, progressive ataxia, and spastic paraplegia. Post-mortem findings showed a striking similarity in the lesions of the central nervous system to those found in Wernicke's disease. That aneurin deficiency is the cause of Chastek's paralysis has been established beyond doubt by the work of Green and his co-workers[3] in America and Kringstad[4] and other workers[5] in Norway and Sweden. The American observers were able to produce the paralysis at will by feeding the silver foxes on a diet containing more than 10% of raw carp. They were also able to prevent the appearance of the disease by supplementing the diet with large quantities of aneurin, exceeding 10 mg. per animal per day. These results indicate that raw fish has the singular property of inactivating aneurin, either by destruction of the vitamin or by a process of adsorption which renders it unavailable to the animal. The first theory finds support in the work of Spitzer *et al.*,[6] who incubated raw carp entrails with aneurin and observed a destruction of 50 to 100% of the vitamin in 15 minutes. Thus it appears there is an anti-aneurin factor or factors in raw fish, destroyed by cooking. The existence of antivitamin factor is not limited to aneurin. At least two other examples of antivitamins have been found in connexion with biotin and vitamin E. The antivitamin of biotin is present in raw egg white, from which it has been isolated in the form of a protein which has received the name "avidin." Avidin acts by combining with biotin to form a stable complex which is not available to the organism. An antivitamin E factor has been found in cod-liver oil which is capable of destroying the vitamin when the two are fed together. Possibly still other antivitamin factors may be brought to light. A knowledge of these factors may be of great value in explaining many as yet obscure nutritional diseases.

HYPOGLYCAEMIA FROM PROTAMINE INSULIN

Recent correspondence and articles in this *Journal* have raised the question whether insulin hypoglycaemia in diabetics is becoming more frequent in both its minor remediable forms and its occasional fatal outcome, and whether the use of protamine-zinc-insulin is responsible. Ever since insulin has been used minor hypoglycaemia has been common, but recorded fatalities have been surprisingly rare, perhaps because seldom published, as they mostly depend on a discreditable and avoidable mistake on the part of either patient or doctor. But the increased incidence of grave hypoglycaemia since the introduction of delay-action protamine insulin is understandable and merits discussion.

The effect of a reduction of blood sugar falls on the central nervous system, and the mechanism and pathological results are becoming known. Glucose is the main if not the only, fuel of the brain, and its metabolism and vital process stop without it. If the blood-sugar supply is cut off by insulin for a few hours (say 4 to 8) irreversible nerve-cell changes may occur which cannot be removed by the restoration of the blood sugar—fortunately an extremely rare event. Now soluble insulin, in use for 20 years, often causes hypoglycaemia in inappropriate doses by its quick and strong action, usually 4 to 6 hours after injection; but the effect is so short-lived that prolonged hypoglycaemia is unlikely, and spontaneous recovery tends to occur even without the administration of sugar, although it should be given promptly on diagnosis. In contrast, the prolonged action of protamine-zinc-insulin, although probably causing hypoglycaemia less frequently, keeps the blood sugar low when hypoglycaemia occurs, prevents spontaneous recovery, and is more likely to damage brain cells. In the vast majority of such incidents, however, glucose or sugar (1 oz.) produces complete recovery, but may have to be repeated to prevent relapse. Another danger with protamine-zinc-insulin is the temptation to give too much unless the limitations of its action are realized. It is weak in its action, and the active insulin liberated from the depot injection is often too little to prevent glycosuria after meals, although it clears the sugar during the night's starvation. If the dose is raised in an attempt to control the day's glycosuria, it has little effect except to cause hypoglycaemia at night, often just before breakfast. It is usually unwise to give more than 30 to 40 units of protamine insulin without careful investigation, and no more should be given than is sufficient to clear the urine secreted before breakfast. If on this dose heavy glycosuria occurs by day, added soluble insulin must be given and not more protamine insulin. The occurrence of hypoglycaemia at night has led some doctors to abandon the use of protamine insulin and to put their patients back on two doses of soluble insulin. When, however, the nature and action of protamine-zinc-insulin are appreciated and it is properly used, there seems no reason to withhold the benefit from most patients of only one injection a day instead of two.

Another, and preventable, cause of hypoglycaemia is the mistakes that arise from confusion over the different strengths of insulin solutions on the market—namely, 20, 40, 80 units per c.cm. Serious mistakes, too, are caused by the wide diversity of markings on syringes used for the injection of insulin: it is not uncommon to find some less intelligent diabetics taking twice or half the number of units intended by the doctor. Such errors could be minimized by the use of a standard insulin syringe throughout the country, and it is most important that the actual dose should be checked and demonstrated to each patient, not merely as so many units but in marks on their own syringe of the strength of insulin prescribed.

Another, and probably the main, cause of insulin hypoglycaemia is the fact that the best dose of any type of insulin, even on standard diets, is not a uniform but always an individual one, and a dose that may cause hypoglycaemia in one patient may be insufficient even to prevent diabetic coma in another more severe case. The establishment of the optimum dose in some cases requires a short period of close study which cannot be carried out at home, nor indeed in most general hospitals. In many cases, therefore, imperfect treatment magnifies the difficulties of insulin treatment and obscures its benefit, so that chronic invalidism may persist where a full and useful life could be achieved. This state of affairs can hardly be rectified until sufficient centres for skilled diabetic treatment are available to provide in- and out-patient treatment for many, if not for most, diabetics.

HAEMOPHILIA IN ANIMALS

Haemophilia is a well-known disease among white races, and occasional cases of varying authenticity have been reported in men with skins of other colours. A. G. Hogan, M. E. Muhrer, and R. Bogart[1] suggest that a similar disease may occur in another species of mammal. A number of related animals in a herd of swine died from haemorrhage, either spontaneous or after minor trauma. The ordinary bleeding time, the platelet count, and the prothrombin time were all normal in the affected animals when compared with normal members of the same herd. The clotting time of venous blood was greatly prolonged, and the platelets, unlike those from normal animals, were slow to agglutinate and disintegrate *in vitro*. Thus the haematological findings are those of human haemophilia, but unfortunately no mention is made of the sex of the affected swine or whether any of them had haemarthroses. If this disease of pigs is in fact the haemophilia it seems to be, the fundamental lesion which has baffled so many investigators of human haemophilia ought soon to be uncovered.

A. L. Copley and J. L. Lalich[2] tried to produce a haemophilia-like condition experimentally by the injection of heparin into mice. The animals tended to suffer from spontaneous haemorrhages, and had a prolonged clotting time, a normal platelet count, and a bleeding time usually normal. As all the evidence goes to show that the prolonged clotting time in human haemophilia is not due to an anticoagulant in the blood, it is *a priori* unlikely that the heparinized mice suffered from anything really like haemophilia, and an examination of the experimental evidence, which is collected in a rather misleading table, does not support the authors' interpretation of the data. For instance, it is stated that the prothrombin content of heparinized blood, like that of haemophilic blood, is normal.[2] Anyone who has ever tried to estimate the prothrombin in heparinized blood by the one-stage method knows how very differently from haemophilic blood heparinized blood behaves. The spontaneous haemorrhages do not resemble those found in human haemophilia either. The animals developed haematomata at the site of subcutaneous injection of heparin, but no attempt seems to have been made to control the *p*H of the heparin, which is usually strongly acid. A few mice which had been heavily heparinized licked the clot away from the site of the puncture which was made for determination of the bleeding time, and then suffered from prolonged bleeding which occasionally proved fatal. This is actually in contrast to what happens in haemophiliacs, in whom the clot is not firm enough to prevent spontaneous resumption of bleeding. The really striking point in these experiments is that the bleeding time was usually normal in the presence of a greatly prolonged clotting time. This is doubly significant, because the bleeding time was estimated by puncturing the tail vein, which would tend to give a long bleeding time, and the clotting time was estimated on capillary blood, which, because it is contaminated with tissue juice, gives a relatively short clotting time. The fact that the bleeding time was often less than one two-hundredth of the clotting time in these heparinized mice is further support for the view put forward so cogently by R. G. Macfarlane[3] that haemostasis is first secured by vascular contraction and is only secondarily dependent on the coagulation of the blood.

TRANSFUSION OF BOVINE PLASMA AND SERUM

Experience in treating the casualties of total war has emphasized the need for combating shock by the transfusion of fluids with a high protein content: human blood, plasma, and serum have all proved their worth. In this country there has been no lack of human material; in the U.S.A. it has been felt the demand might outrun the supply. Attention has therefore been directed to the use of bovine plasma and serum. The first detailed published report[4] from the University of Minnesota describes the use of bovine products in 120 cases. As the authors state, the incidence of reactions was sufficient to contraindicate any clinical use of whole bovine serum or plasma. Both were shown to contain haemolysins and haemagglutinins to human red cells. Most of the haemolysins and about 50% of the haemagglutinins could be removed by adsorption on human red blood cells. By so doing the incidence of reactions was reduced from 66.6% to 24.5%. A preliminary skin test was done on all patients, using 0.1 c.cm. of 1 in 10 dilution of serum with normal saline. In a preliminary series of observations patients who showed pronounced skin wheals were found not to take serum well and were therefore not used subsequently. Following the skin test 0.1 c.cm. of bovine serum diluted to 1 c.cm. with normal saline was given intravenously. Several hours later, if no reaction occurred, 1 c.cm. diluted to 10 c.cm. with normal saline solution was given intravenously; next day 5 c.cm. diluted to 10 c.cm. was given, and, somewhat later, 50 c.cm. diluted to 100 c.cm. If no reaction occurred, amounts of 250 c.cm. diluted with an equal amount of saline or 5% dextrose were injected, the rate of administration being slow. About 50% of reactions were febrile in character, usually indicated by a chill one-half to 1 hour after the start of the injection. Other reactions, such as immediate urticaria, oedema of eyelids, flushing of skin, backaches, gastro-intestinal upsets with diarrhoea and vomiting, dizziness, and severe anaphylactic reactions, made up the remainder. No significant difference was found between serum and plasma. Three severe anaphylactic reactions occurred with extremely small doses of 2 c.cm., 0.1 c.cm., and 0.1 c.cm. respectively. Skin tests gave no indication of this sensitivity. Delayed reactions, characterized by generalized urticaria, oedema, and gastroenteritis, occurred in about 60% of patients 3 to 10 days after the final injection. They lasted 48 to 72 hours. The majority of the patients suffered from inoperable carcinoma; two patients with shock were treated with success. Six patients were given re-injections of whole bovine plasma and serum after variable intervals, and these showed an anaphylactic type of response.

The authors suggest that the preparation of a satisfactory product of bovine albumin from which the globulin fraction has been eliminated completely may prove a safe and satisfactory blood substitute. Milton E. Veldee[5] has recently reported that E. J. Cohn[6] has prepared such an albumin fraction from human serum which has given satisfactory results on clinical trial. The advantages of the fractionation of human serum which has proved its value when given in bulk are not altogether clear, but the value of such treatment in the case of a foreign serum are more obvious, and further reports will be awaited with interest.

DEVELOPMENT OF THE EMERGENCY BLOOD TRANSFUSION SCHEME

BY

L. W. PROGER, M.R.C.S.

Medical Officer in Charge of Blood Transfusion at the Ministry of Health

Peacetime Service.—In this country the blood donor has always regarded his work as a voluntary social service. Twenty years ago, in Camberwell, Mr. R. L. Oliver founded the association of voluntary donors which later became the British Red Cross Transfusion Service—the first of its kind in the world—and this led to the development of a number of similar organizations throughout the country. These organizations undertook to provide hospitals with accredited donors of the required blood group at short notice, and their members were prepared to attend the hospitals at any hour of the day or night. Contributions could be made towards the cost of the service, but the donors were always volunteers. The introduction of blood storage at many of the large hospitals during the past six years was an important advance in technical methods, since tested blood could always be kept ready for an emergency case, and it was no longer necessary to call donors at inconvenient hours. However, the use of individual donors remained general until recent times, and is still the method of choice in the treatment of certain cases.

Pre-war Preparations.—During the months of political tension after September, 1938, recent advances in transfusion methods were constantly under discussion, especially in view of the success achieved in the Civil War in Spain, where stored blood was carried to Army medical units in the field and was also used for the treatment of air-raid casualties in the large cities. It seemed clear that the quantity of blood required under the conditions of modern war would be beyond the scope of the peacetime donor services, and that special arrangements would be required. London, with its vast concentrated population dependent on a complex system of transport and supply, presented a transfusion problem of special importance, and the Medical Research Council undertook to establish, on behalf of the Ministry of Health, four Blood Supply Depots in the outer suburbs. These depots, which are still under the direct control of the Council, were designed to store blood collected from panels of voluntary donors enrolled in the Home Counties, with the object of supplementing the local arrangements of hospitals in the central area, which were more likely to become disorganized. At the same time arrangements were made to establish an Army Transfusion Service, and it was agreed that since this service would enrol all the available donors in the South-Western Counties it would also supply the emergency needs of the civilian hospitals in the area.

The First Year of War.—From the outset stores of blood were available, and during the early months of the war the four London depots were enabled to perfect their arrangements and to carry out valuable research work on the storage and preservation of blood. At the same time the voluntary transfusion organizations throughout the country increased their activities, and emergency blood stores were established in many of the large cities. On the outbreak of war the Army Transfusion Service was faced with the problem of transporting blood to the B.E.F. in France—a problem made all the more difficult by the fact that blood cannot be stored for more than 2 to 3 weeks, and special precautions have to be taken against the damaging effects of shaking in transit. A large reserve store could not therefore be built up so long as there was no demand for its use. On the other hand, the service had to be prepared at any moment to start bleeding large numbers of donors. It speaks highly for the success of the organization that during the first three days of the invasion of the Low Countries approximately 800 bottles of blood were dispatched to France, enabling the forward medical units to be adequately supplied and the base store to be replenished. Although the forward units were soon isolated from further supplies, some 500 transfusions were given during the retreat from Belgium and the evacuation from the beaches under the most adverse conditions.

Introduction of Plasma and Serum as Substitutes for Blood

In America experimental research on blood substitutes has demonstrated that plasma—the fluid portion of blood after removal of the red cells—provided a reliable substitute for whole blood, and had the advantage that it could be stored for many months without deterioration. In addition, its recovery avoided the wastage of blood which was not used within the safe storage period, and, moreover, plasma could be safely given to patients of any of the four blood groups. This discovery was of the greatest importance, especially to the armed Forces which required supplies in distant theatres of war. The first American product—plasma-saline—had certain theoretical disadvantages in that the method of preparation required considerable dilution, which not only doubled the weight and bulk to be transported but also increased the volume of the effective dose to be administered. Moreover, Federal Government regulations required that antiseptic should be added to ensure sterility, and many considered that this might be injurious to debilitated civilian casualties. Investigations continued, and the Army Transfusion Service developed a method by which undiluted plasma could be bacteriologically filtered, thus ensuring a clear sterile product which could safely be transported over-seas without the need for refrigeration. The value of serum—the fluid separated from blood after it has clotted—was being investigated by the Medical Research Council, especially in relation to the treatment of shock resulting from air-raid casualties and burns, and this also proved to be a valuable substitute for whole blood. Serum is more easily filtered than plasma, and has similar keeping properties, but, since the blood has to be specially drawn for its preparation, it does not have the advantage that plasma has in being a natural recovery product from the blood stores.

The Regional Scheme

After the capitulation of France and the return of the B.E.F. in June, 1940, the position called for urgent review, since no part of the country could now be regarded as more than relatively immune from air attack. The Ministry of Health therefore undertook to co-ordinate and extend, where necessary, the blood transfusion services throughout England and Wales, with the primary object of ensuring that an adequate supply of transfusion fluids and standard apparatus was made available for the treatment of casualties. Nine Regional Blood Transfusion Officers were appointed. The schemes developed under their direction, with the organizations set up in the London area by the Medical Research Council and the Army Blood Transfusion Service centred in a South-Western town, cover the whole of England and Wales. Similar organizations have been established in Scotland and Northern Ireland. The schemes developed by the Regional Blood Transfusion Officers provide for financing the enrolment and testing of the additional donors required to meet emergency needs, the supply and distribution of the standard apparatus, and the establishment of laboratories for the preparation of the apparatus and the filtration of plasma and serum. Thus, during the past year there has developed a unified scheme in which the voluntary donor associations, the hospitals, the local authorities, and the Ministry of Health are co-operating with the fighting Services to provide a nation-wide emergency transfusion organization. Adequate blood stores are being maintained at important points throughout the country, so that every casualty hospital can obtain supplies to supplement its own resources. Plasma is recovered from these stores, so that wastage is reduced to a minimum, and, as stocks of plasma are built up, so each hospital will have its own reserve. Thus even the remotest hospital will have transfusion fluids ready for immediate use, leaving time for blood to be brought from the nearest stores should this be required.

Research work is co-ordinated by a representative committee of the Medical Research Council, which keeps in close touch with work going on in the Dominions and America, so that each centre is kept informed of the most recent developments.

Introduction of Dried Plasma and Serum for Transfusion

The preservation of unstable fluids such as milk by drying has been the subject of investigation for many years. More recent research, both in America and in this country, has shown that even more unstable fluids may be preserved without change by drying from the frozen state, and this knowledge has now been turned to the use of the Transfusion Services. In January, 1940, the Medical Research Council extended its experimental serum-drying unit, since it was foreseen that a demand for dried transfusion fluid by the fighting Services would arise. This unit had developed a process whereby large volumes of serum or plasma could be treated and a high degree of dryness obtained. The method of drying from the frozen state reduced protein changes to a minimum, and tests indicated that the dried product was capable of preservation for many years without deterioration. Moreover, the dried product could be quickly reconstituted for use by the addition of the appropriate quantity of distilled water.

When the Ministry of Health Regional Blood Transfusion Scheme was under consideration in July, 1940, the Wellcome Trustees offered the M.R.C. a grant to meet some urgent national need. The Council suggested that the grant should be used to provide another drying plant. Towards the end of the year the Army Blood Transfusion Service arranged to set up a similar plant to meet the growing needs of the oversea Forces. In conjunction with the Medical Research Council they devised an improved method for the freezing of the plasma or serum in the standard bottle preparatory to the drying process. By rotating the bottle at a high speed in a low-temperature cabinet the fluid was forced on to the sides of the bottle and freezing occurred almost instantaneously. This spin-freezing method produces a better-quality dried product which redissolves more readily than that produced by earlier methods. A supply of transfusion fluids is thus assured in a form which can be dispatched to any part of the world.

Working Arrangements

Co-operation with the Fighting Services.—Close co-operation has been maintained with the transfusion officers of the Army Command areas, from whom much assistance has been obtained during the period of development. The Royal Naval and Air Force Medical Services have also adopted for emergency transfusions the dried products, which are especially suited to their requirements. Arrangements have been made whereby the Home Stations of the R.A.F. may use the facilities provided under the Regional Scheme, so that adequate supplies of stored blood and plasma will be available. The R.A.F. Mobile Transfusion Team is giving valuable assistance in maintaining supplies.

The Large-scale Bleeding of Donors in Wartime.—In normal times a donor can always be found to attend at a hospital when needed, but, when dealing with the large numbers required to build a reserve of plasma and to maintain war emergency blood stores, sufficient donors are seldom able to attend during working hours, as the hospital may be a considerable distance from their work. Moreover, even the large hospitals cannot always be relied upon to provide the necessary staff and accommodation without interfering with their normal duties. For this reason mobile teams have been established; these can set up bleeding centres at places convenient to the donors, such as first-aid posts, village halls, cottage hospitals, or at factories. Even in these difficult times factory managements have been most helpful, and in many cases the factory organizes its own donor panel and provides on regular days the agreed number of donors from members of the staff chosen so as not to interfere with production.

Publicity Campaign for Donors.—Hundreds of thousands of volunteers have been enrolled and many thousands have already given their blood, some on more than one occasion. The difficult task of launching publicity campaigns strong enough to attract the number of donors required and yet restricted to the desired locality has been successfully accomplished with the valuable assistance of the Press and local voluntary associations. Donors sometimes remark that, while their services have not yet been called upon, active campaigns for more donors are proceeding in other districts. It will be appreciated, however, that the donor panels should bear some relation to the density of the population. To provide for the constant movement of the population, for local disturbances due to air raids, and for other factors which interfere with the attendance of donors at the centres, the panels must be larger than the needs of the moment appear to justify.

Donors' Obligations.—The calling up of large numbers of donors, the assembly of the necessary staff and equipment at the bleeding centre, and the distribution of the blood collected is a complicated matter involving much clerical work and planning in advance. This is not always appreciated by donors, who may think, especially in quiet periods, that their services are not really needed. It occasionally happens that only half the number of donors called arrive at the bleeding centres. This may result in the team of doctors and nurses being kept unoccupied for several hours, the work of the filtration laboratory staff being held up, a promised consignment failing to be sent to the drying plant, or a group of hospitals being kept short of supplies of fresh blood. In addition, there is the extra clerical work in tracing the absent donors and rearranging their index cards. With adequate donor panels it should not be necessary to call a volunteer more than twice a year provided all the donors are prepared to do their utmost to attend when required.

The Present Position

Full advantage has been taken of the relatively quiet period during the past twelve months to build up stocks of plasma, so that even the remotest hospital will have its own emergency reserve. Improvements in the filtration process have been introduced, and contributions are being made towards the supply of dried products for the fighting Services. One of the effects of these emergency measures, and the wider understanding of modern methods, has been the increasing use of transfusion in the treatment of the ordinary sick and injured in the hospitals. Although the need for building up of emergency plasma stocks has now largely been met, the blood stores must be maintained. This will entail the continued bleeding of donors, but now that the filtration and drying processes are in full operation there need be no fear that the blood will be wasted.

Accurate figures have been difficult to obtain, but the following estimates give a fair picture of the present position:

Up to the end of 1941 over 800,000 donors had been enrolled, but, for a number of reasons, a large proportion of these are not always available on the active lists. During the last half of 1941 some 180,000 pints of blood were collected. 32,000 pints of this blood were used in hospitals for the treatment of both Service and civilian patients, including war casualties; the remainder has been converted into plasma or serum. Over 10,000 pints of this plasma and serum have been used for transfusions, a proportion has been dried for the use of the Navy and Air Force, and the remainder has been distributed among the hospitals to provide an emergency reserve. In addition to this, the Army Transfusion Service has collected over 100,000 pints of blood for the preparation of dried plasma for the use of Army medical units over-seas, apart from the provision it has made for supplying civilian hospitals in the South-Western Region.

Success depends in a large measure on the maintenance by the donors of that spirit of voluntary social service shown so conspicuously by the first associations of twenty years ago.

The Chartered Society of Massage and Medical Gymnastics is arranging to hold its annual congress on Friday and Saturday, September 18 and 19, in the Great Hall of B.M.A. House, Tavistock Square, W.C. On September 18 at 2 p.m. Prof. J. A. Ryle will lecture on "The Re-making of Man"; at 3.30 Prof. F. R. Fraser will lecture on "The Place of Rehabilitation in the Treatment of Patients," and at 6 Lord Horder, President of the Society, will give the founders' lecture on "Rehabilitation: the Part Played by Physical Medicine." On September 19 at 10 a.m. Surgeon Lieut.-Commander J. Bunyan will lecture on "The Treatment of Wounds and Burns by the Envelope Method," illustrated by a film, and at 11.30 Dr. Vaclav Benes on "Physical Training Organization in Czechoslovakia." These meetings are open to all medical practitioners. The annual general meeting, open only to members, will be held at 2 p.m. Further particulars may be had from the secretary, C.S.M.M.G., Mount Lodge, Amersham, Bucks.

DEHYDRATION OF FOODS

The Nutrition Society and the Food Group of the Society of Chemical Industry held, in the Great Hall of B.M.A. House, their first joint meeting on July 25. The occasion was notable for this itself, indicating collaboration in those areas of scientific and technical inquiry where the territories of nutritionists and food technologists overlap. The meeting was also of particular interest in that it provided an occasion for members of the scientific staff of the Food Investigation Board (of the Department of Scientific and Industrial Research) to report to an expert audience the results of work on which they have been engaged during the last three years, work that may have a profound effect on the nutrition of the people, in peace as well as in war.

Sir EDWARD APPLETON, Secretary of the Department of Scientific and Industrial Research, who took the chair at the morning session, drew attention to the part played by his Department in arranging and supporting the laboratory work necessary as a foundation for subsequent technological development. Dehydration processes were to be regarded as a means of avoiding the annual importation of 3 million tons of water included in imported foods. It had the further advantage of making possible the storage of foodstuffs at ordinary temperatures without refrigeration, as well as facilitating transport, which Sir Edward described as "storage on the move." He also referred to the effect of pre-drying treatment and to the quality of the raw material as having an important influence on the finished product, and necessitating scientific investigation just as much as conditions during drying and methods of packing. In this connexion he quoted Sir William Hardy's famous dictum that you must be clear about the biology before you come to engineering. Sir Edward paid a tribute to Mr. ERIC BARNARD, Director of Food Investigation in the Department, to Dr. FRANKLIN KIDD, Director of the Low Temperature Research Station at Cambridge, where the technical work is being carried out, and to Dr. LESLIE HARRIS, Director of the Dunn Nutritional Laboratory in Cambridge, who collaborated by arranging for the conduct of tests to ensure that the processes used should not lead to serious loss of nutritive value. Assistance had also been received from firms and individuals in industry, and Sir Edward hoped that this collaboration would continue.

Principles and Practice

Dr. FRANKLIN KIDD then outlined the principles and practice of food dehydration. He emphasized the importance of giving the fresh foods a preliminary heat treatment before submitting them to any of the approved processes of dehydration. The destruction of enzymes, especially those catalysing the decomposition of vitamins, was probably the chief effect of this blanching or scalding, but the preservation of good appearance and palatability would seem also to be partly due to that treatment. Dr. Kidd emphasized the need for reducing the volume as well as the weight by processes of dehydration, so that transport space might be minimized. Stabilization of dehydrated foods was secured by the exclusion of oxygen and moisture, and sometimes by the use of antioxidants during processing; exclusion of certain catalytic metals, particularly copper, was also sometimes potent in improving quality and stability. Attention had to be paid both to upper and to lower limits of temperature, as well as to the need for removing moisture as rapidly as possible. Of the various methods of drying, to which Dr. E. C. BATE-SMITH called attention in the second paper, warm-air drying in tunnels appeared at present to be the most practical.

Results with High-protein Foods

Dr. BATE-SMITH then presented a paper of which he, Dr. E. M. CRUICKSHANK, and Dr. J. G. SHARP were co-authors. After describing six different types of drier, three of them steam-heated, with or without vacuum, and the other three dependent upon moving currents of air, he dwelt briefly on the special features of meat and eggs, determined by the fact that they were high-protein foods and not primarily sources of heat-labile vitamins. The drying of meat at 80° C. in properly constructed plant and with proper control involved no losses in palatability or in the biological value of the protein and only small losses of aneurine, in which meat (except pork) is, in any event, not particularly rich. The technique of drying makes it impossible to dry meat except when relatively finely minced, and the dried meat products so far made available are, therefore, limited to use in dishes like mince and cottage pie. As those attending the meeting had an opportunity of establishing for themselves during the lunch interval, the palatability of these dishes made with dehydrated food is no whit less than that of the corresponding dishes made with fresh meat. The need for dried egg powder to be "soluble"—that is, for it to reconstitute with water to something as close as possible in physical properties to the mixed white and yolk of fresh eggs—sets a limit to the processes available for drying. Spray drying conserved the whole of the fat-soluble vitamins in egg, though it involved some losses of aneurine, but the best commercial products from America were equal in nutritive value to equivalent quantities of home-laid fresh eggs. Assessment of palatability, a complex phenomenon, had been made possible by the use of tasting panels, which gave unexpectedly uniform results. Certain problems still awaited solution, particularly the varying deterioration during storage, some samples being stable for periods of a year or longer and others losing their attractiveness fairly rapidly. Storage in closed containers was essential in order to exclude moisture, but it had not been found necessary to pack egg powder in an inert gas.

Dr. G. A. REAY of the Torry Research Station, Aberdeen, describing the work on the drying of fish conducted under his direction, said that freezing methods had not been found satisfactory, although they marked a very great improvement on traditional methods of slow sun- or air-drying. By roller-drying a fish "lace" was produced, and certain types of this had been found very suitable for fish-cakes. In general, however, kiln-drying in the kind of heater used for kippering had been found the best method when following an appropriate period of pre-cooking. Minced fillets were treated in this way, and the resulting product permitted, as was shown by figures that Dr. Reay quoted, a very large saving of storage and transport space. During the discussion on this part of the meeting, Mr. NEVILLE WRIGHT of the New Zealand High Commissioner's Office referred to the immense saving in shipping space that would be effected if more dried meat were produced in the Dominions and shipped to this country in the dehydrated form. Much work needed to be done, and a good deal was already in hand, to bridge the gap between laboratory experiments and commercial production. Data on plant design were not yet available, and it would be well to secure close collaboration with engineering firms with a view to producing the most suitable plant in the shortest possible time. Investigation was also required into the engineering side of packing dehydrated foods. Mr. Wright made a strong appeal for an international exchange of information on these and allied matters.

After Dr. A. S. MACFARLANE had spoken about the theoretical advantages and the practical difficulty of freeze-drying and the bulkiness of dehydrated foods that was essential if they were to reconstitute properly, Dr. R. T. COLEGATE, demonstrated the difference between air drying and high-vacuum drying with an exhibit of vacuum-dried gluten having a phenomenally high volume-to-weight ratio and yet easily broken down into a powder. This demonstration evoked considerable applause from an audience that was obviously now prepared not only to consume its lunch, but also to samples dishes made with dehydrated foods. This was done after contributors to the discussion had replied, and the dishes made from reconstituted dried meats, dried carrots, dried cabbage, and dried potatoes were highly praised. Bench demonstration in the morning of rehydration of cabbage reminded one very much of the "magic gardens" in the tumblers of one's youth, but differed in that the latter have no characteristic aroma. A similar demonstration with a block of dehydrated potatoes, which was rapidly converted into a good dish of the mashed vegetable before the eyes of the expert and critical audience, was one of the features of the afternoon's meeting, when the chair was taken by Dr. H. E. Cox, Chairman of the Food Group, in the unavoidable absence of Dr. L. H. LAMPITT.

Value of Pre-heating

Discussing the dehydration of vegetables, particularly of cabbage, but also of carrots and potatoes, Dr. W. J. R. Allen said that the preservation of colour and of ascorbic acid in cabbage appeared to be effected by similar means, including scalding before drying, use of sulphite, and choice of appropriate drying temperatures. Dr. L. W. MAPSON, who, with Dr. J. BARKER, was co-author of this paper, when replying later to the discussion, emphasized the importance of the technique of serial scalds, whereby there was built up for the pre-heating process a solution sufficiently rich in ascorbic acid and other solutes to prevent serious loss from the batch of material being scalded. Particularly interesting was the suggestion that the boiling of carrots in water previously used for the boiling of carrot tops and then strained could actually provide the consumer with a cooked carrot containing more vitamin C than the raw root. Dr. Allen stated that no loss of carotene occurred during the proper drying of carrots, and that the strain of potato used must be taken into account when determining the technique of drying, for this affected the final product. He also gave the warning that losses of aneurine, as might have been expected from chemical considerations, unlike those of ascorbic acid, were not mitigated by the use of sulphite. Mr. L. U. CHARLEY, who opened the discussion on this paper, emphasized that dehydration offered possibilities of saving food that might otherwise go to waste, and instanced the possibility of using the outer leaves of cabbages, which appear to be very much softened by the dehydrating process, and the large and mis-shapen carrots which normally may not find a market. Mr. T. RENDLE laid stress on the importance of pilot plant work, and Mr. B. G. MCLELLAN on the possibilities of domestic drying. In his reply, Dr. Mapson also indicated how the use of dried foods, by expediting procedure in canteens and other communal kitchens, might effect a further saving in nutrients that were progressively destroyed on the hot-plate.

Sir JOSEPH BARCROFT presented a final paper on the place that dried foods might and ought to have in the general food economy of nations. In his opinion, desiccation of foods, because of the considerations that had been put forward at the meeting, would put a premium on quality; only the inefficient and unscrupulous producer of fresh food need fear competition from the new technique. Sir Joseph also discussed the two different kinds of glut, the seasonal and foreseeable, and the casual and unpredictable, and expressed the view that the use of dehydrated foods in the kitchen might at one and the same time make communal feeding easier, and help to put the family as an institution on its legs again. Squadron Leader T. F. MACRAE followed this more theoretical consideration with some practical data on experience of dehydrated foods in the R.A.F. He was able to show, from experiments with considerable numbers of personnel as well as from laboratory tests, that these foods are not at all inferior in palatability or nutritive value to fresh counterparts. Indeed, it would not be going too far to claim that the dehydrated foods, as consumed, had a higher content of ascorbic acid and were less liable to be left on the plate than were the cooked fresh foods.

Dr. JOHN HAMMOND discussed the effect of the possible bearing of dehydration, with an adequate and planned distribution of dehydrating plants, on agricultural production, and anticipated that it might well lead to increased food production in hitherto unexploited districts. In the absence of refrigeration, shortage of storage space in certain countries had been a bugbear to those planning post-war relief work, and dehydrated foods might help to save the situation. Greater availability of semi-prepared foods might help to reduce the drudgery of household labour and lower the cost of high quality food, thus also making out-of-season products available to people of moderate incomes.

The chairman, Dr. H. E. Cox, in closing emphasized that the subject presented two main problems: the post-war problem, when considerations of costing and economics would play an important part in determining the scope of food dehydration; and the food problem of the present time, when it was a matter of extreme urgency to use all methods so far available to conserve the food of the nation and maintain its nutritive value. This concluded proceedings that had obviously been of outstanding interest; the Great Hall was full, and at certain times there were numbers of members or visitors in the gallery or standing at the back of the hall. Something approaching 500 people must have attended in the course of the day, and these included a very high proportion of those most active in the parallel fields of nutritional research and food technology. The day's work was of value not only for the old information that it summarized and the new that it made public for the first time, but also for the contacts that it initiated or renewed between groups of workers, all of whom are essential for the full application of scientific knowledge to the problem of nutrition and human health.

DIPHTHERIA IMMUNIZATION CAMPAIGN

The Government is opening a campaign for more complete immunization of the child population against diphtheria. To inaugurate the campaign in the London region the Ministry of Information summoned a press conference at County Hall, when addresses were given by three medical officers of health. Dr. W. Allen Daley, medical officer of health of the London County Council, said that in 25 out of the 29 metropolitan boroughs immunization was now carried out at the schools, either by the county council or borough council medical officers, while school medical officers, nurses, and teachers were co-operating to induce parents to sign the consent form. He estimated that 36% of the children now in London were protected against diphtheria, a great advance on the position in 1937, when the figure was 5.3%, but far below the 75% which would be judged satisfactory. He mentioned the examples of Scotland (where the figures were 54% for the "under fives" and 71% for school children), of Montreal and Hamilton in Canada, and of New York. In New York an intensive campaign was begun in 1929, when the deaths from diphtheria were 463 in the year, and by 1940 they had declined progressively to 10. In the county of London the notifications, which were just over 7,000 in 1936, fell to under 2,000 in 1940, and the deaths from 226 to 40, but there was a rise in both notifications and deaths in 1941. Dr. Daley's remarks were supported by Dr. H. Geffen, president of the Home Counties Branch of the Society of Medical Officers of Health, who, speaking of a total of 57 districts in the Home Counties, with a child population of over half a million, said that 35% of those under 5 and 48% of those between 5 and 15 had now been immunized, but the important thing to secure was the immunization of the young child at the age of 1 year or thereabouts. Dr. Geffen said that there was some evidence that parents were deterred from giving consent owing to the experience of the father, if on active service, of an unpleasant inoculation for typhoid or dysentery. It should be emphasized in the campaign that antidiphtheria injections were practically painless and without unfortunate after-effects. He was asked if general practitioners could not be given the means of carrying out free immunization, to which he replied that he agreed in principle, but mass immunization at the municipal clinic was quicker, easier, and more economical. The general practitioner could not deal with large numbers at any one time, and therefore must be provided with a more expensive reagent and one more difficult to make than that which served the purpose of mass immunizations. Dr. G. Macdonald, as representing the Borough Medical Officers Committee, said that all the medical officers were enthusiastically behind the Ministry of Health in this campaign. Diphtheria immunization was beyond the stage of experiment, it was easy to administer, safe, and capable at the very lowest of protecting 90% of the child population submitted to it.

Full details of the Government's programme and a comprehensive guide on the planning of local campaigns are contained in a pamphlet which has been sent to all welfare authorities in England and Wales. The first part outlines the Ministry's central publicity, which will include advertisements in Sunday newspapers and a wide list of periodicals; broadcasts; editorial publicity; trailer films; and national displays in 1,200 shop windows during August. The second part deals with the facilities which are being provided to assist local authorities' publicity, including stereos for local newspaper advertising (which can be obtained free of charge from the Public Relations Division of the Ministry of Health); cinema slides; the sound film 'Defeat Diphtheria"; and a 4-page leaflet, a shop window poster, and a public transport vehicle bill produced by the Central Council for Health Education. Recommendations for local campaigns cover such points as timing and duration, press advertising, press conferences, and supporting material.

APPROVED NAMES OF DRUGS

The General Medical Council has approved names for certain substances which are now being produced, or are likely shortly to be produced, by British manufacturers, in some instances under licences granted by the Comptroller-General of Patents, Designs, and Trade Marks. These substances have hitherto been known under other names, which are given below together with the names now approved. The question of including them in the *British Pharmacopoeia* is under consideration, and if any of them is included the intention is that the approved name given below will be its official title.

Approved Names	*Other Names*
Dienoestrol	Di-*p*-hydroxyphenylhexadiene
Pheniodol	Biliselectan
Ethisterone	Ethinyltestosterone Lutocyclin Lutogyl Pregneninolone Progestoral Proluton C

It is hoped that the early publication of these approved names may lead to their general adoption.

RECENT ADVANCES IN DRUG THERAPY

In an interesting article on recent advances in drug therapy, L. S. Goodman (*Bull. N.Y. Acad. Med.*, 1942, **18**, 112) makes the following observations. The local use of sulphonamide drugs has somewhat overshadowed the fact that their oral administration is a useful prophylactic in the quiescent state of rheumatic fever, in scarlet fever contacts when the Dick test is positive, and in meningococcus carriers—among other conditions. Theophylline is an effective bronchial antispasmodic, as are the synthetic substitutes for atropine—namely, novatropine, eumydrine, syntropan, and trasentin. Referring to the various vitamins now in use, he stresses the need for employing them therapeutically only when there is a definite deficiency. Quinine has been found to be effective in the symptomatic treatment of myotonia congenita. Papaverine is a useful vasodilator in the emergency treatment of arterial embolism. Goodman points out that the newer and purified digitalis glycosides (e.g., the lanatosides A, B, and C) are more expensive than digitalis leaf, and that the burden of proof that they are better than the leaf still rests on those making such a claim. Benzedrine, he notes, is especially useful in the treatment of narcolepsy, and may prove a valuable adjuvant to phenobarbital for epilepsy and to the belladonna alkaloids for post-encephalitic Parkinsonism. He observes that no untoward symptoms have resulted from the treatment of threadworms with phenothiazine (the experience in this country is different). From 1929 to 1941 an extensive research on morphine was undertaken jointly by the National Research Council, the Narcotic Bureau of the U.S. Public Health Service, and the Universities of Virginia and Michigan. Of the many substitutes synthesized, the most promising was "metopon," a methyl derivative of dilaudid.

Goodman observes that the use of desoxycorticosterone or other cortical hormones in the prophylaxis and the treatment of shock is still a questionable procedure. He states that desoxycorticosterone increases the blood volume "by a renal mechanism." But the problem of shock is not loss of circulating fluid through the kidneys, but rather through widely dilated or injured capillaries. Until, therefore, it has been shown that the adrenal cortical hormones influence the distribution of body fluids by affecting the permeability of capillaries, their use in shock must be viewed sceptically.

Correspondence

Megaloblastic Anaemia of Pregnancy and the Puerperium

SIR,—In reply to the letter by Dr. M. L. Thomson (Aug. 15, p. 198), which criticizes our communication of July 11 (p. 31), we beg to submit the following observations.

1. We are in full agreement with the dictum that "discussion demands a clear definition of the 'megaloblast,'" but unfortunately, as your correspondent observes, "dissension exists on this point." We are indeed surprised to learn that Dr. Thomson proposes to confine the term "megaloblast" to the "haemoglobinated" classical megaloblast of Ehrlich. The type "A" megaloblast of Israels is described by this author as a large cell with dark blue (non-haemoglobinized) cytoplasm, which in pernicious anaemia may constitute as many as 41.8% of the total marrow cells in sternal puncture films. Your correspondent is apparently labouring under the impression that all large basophilic red cell precursors are "proerythroblasts." If this be so we would suggest that before undertaking to publicize the haematological doctrines of Israels he should seek further instruction from his mentor.

In our view the adjective megaloblastic as applied to marrow films is warranted when a high proportion of the red cell precursors are of a primitive type—i.e., large cells with abundant basophil cytoplasm and a large nucleus displaying a finely reticulated nucleoplasm. Such cells may appear occasionally in many conditions, but in our experience are only found in large numbers in anaemias due to deficiency of the liver principle. In his published descriptions Israels distinguishes his type "A" megaloblast from the proerythroblast solely by certain details of nuclear morphology. We are of the opinion that these distinguishing features are not sufficiently constant or well defined for their ready recognition. However, from the practical point of view this is of little importance, as the proerythroblast of Israels is not found in considerable numbers in marrow films except in conditions where megaloblasts also are numerous. Having exchanged slides and engaged in an amicable and, we trust, mutually helpful correspondence with Israels, we feel that although we may differ from him on certain cytological points of considerable academic interest we are unlikely to disagree over the recognition of a megaloblastic marrow film.

We admit that the value of our paper might have been enhanced to haematologists by the inclusion of photomicrographs and detailed cytological descriptions, but as the paper was addressed primarily to practising clinicians we did not consider that such a course was called for in view of the need for economizing in space, and, furthermore, because detailed illustrated descriptions of the erythroblast series of cells had recently been published by us in the *Quarterly Journal of Medicine*, to which a reference was given in our paper.

2. Your correspondent takes exception to the inclusion in our series of 3 cases in which sternal puncture was not done. That sternal marrow films were not available in these 3 cases is regretted by none more than ourselves. Perhaps we should have omitted these cases, but in view of the rarity of this type of anaemia of pregnancy we did not consider it unreasonable to include them, as in their peripheral blood findings, clinical features, and response to treatment they displayed such a similarity to the 13 cases in which the sternal marrow was investigated. We fully admit that in these 3 cases concrete proof of the anaemia being megaloblastic is lacking, and if Dr. Thomson chooses to regard a severe anaemia with a colour index of 1.33 which responded with a reticulocyte crisis to an injection of liver extract as normoblastic in origin, he is obviously entitled to his opinion. Presumably he refuses to regard his cases of Addisonian pernicious anaemia as megaloblastic unless sternal puncture has been performed.

3. Your correspondent inquires on what grounds was our Case 9 included as a megaloblastic anaemia. It was regarded as a megaloblastic anaemia because in the sternal marrow film large numbers of megaloblasts were present. Although many

normoblasts were also present in the bone marrow this is to be expected when the red cell count is over 3,000,000. The relative increase of normoblasts in association with a low colour index (0.75) was attributed by us to a dual deficiency of liver principle and iron, a combination which in our experience not uncommonly occurs.

The further criticism of certain of our cases in which sternal puncture could not be performed before the injection of liver extract had been started, we answer by stating that in each case the cytological findings were fully consistent with those observed by us in cases of Addisonian pernicious anaemia at varying time intervals after initiation of liver therapy.

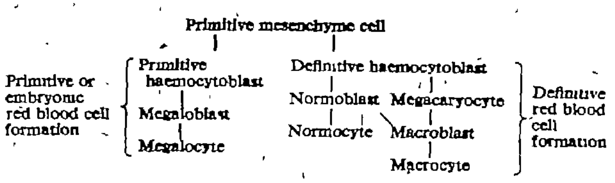
4. Your correspondent's dogmatic and unqualified statement that "the usual pernicious anaemia of pregnancy clears up after pregnancy" is, we consider, dangerous and unscientific, for unless it is realized that a considerable proportion of such cases may require intensive prolonged treatment and maintenance of life with blood transfusions, lives will be lost unnecessarily. It would be interesting to know upon what grounds he names such anaemias "pernicious," and whether he has studied their sternal marrow films.

In conclusion, we too would enter a plea. Although the history of haematology rivals that of theology in its sectarianism and doctrinal intolerance, surely the time has come when clinical haematologists should preserve a sense of proportion in their reactions to technical controversy. The heat engendered by discussions on cytological minutiae should not be allowed to obscure a clear appreciation of what is and what is not important in its practical application to diagnosis and treatment of diseases of the blood.—We are, etc.,

Edinburgh

L. S. P. DAVIDSON.
L. J. DAVIS.
JAMES INNES.

SIR,—Embryologists have for long recognized that in the mammal there are two types of red blood cell formation—the primitive and the definitive. The primitive is concerned with the development of primitive mesenchyme cells into primitive haemocytoblasts and thereafter into megaloblasts and megalocytes; the definitive with their differentiation into definitive haemocytoblasts and thereafter into macroblasts and macrocytes, normoblasts and normocytes. These changes may be represented schematically as follows:



Primitive mesenchyme cell
Primitive or embryonic red blood cell formation
Primitive haemocytoblast
Megaloblast
Megalocyte
Definitive haemocytoblast
Normoblast
Megacaryocyte
Normocyte
Macroblast
Macrocyte
Definitive red blood cell formation

Ehrlich held the view that in pernicious anaemia red blood formation had reverted to the primitive type; according to him also the megaloblast was a large haemoglobin-containing cell with a leptochromatic nucleus, which was to be found in small numbers in the circulating blood of patients with pernicious anaemia. This cell ripened into the non-nucleated form, the megalocyte. At a later date Nägeli described two other cells of definitive lineage—the macroblast and the macrocyte—as occurring in the blood in certain conditions. Where this takes place the marrow is organically and physiologically sound, but, owing to certain adverse influences, the removal of which brings about restitution to normality, it is for the time being functioning abnormally. In pernicious anaemia, however, with its megalocytic blood formation, the marrow is the subject of organic disease without known cause capable of removal.

Peabody, who was regarded as the authority on the subject, was of opinion that the predominant cell in the marrow in pernicious anaemia cases was the megaloblast. In 1928, however, I pointed out that his megaloblast was in reality a haemocytoblast; and later (1934) Turnbull expressed a similar opinion. There is, in fact, no justification historically, morphologically, or otherwise—indeed, on the contrary—for supplanting the haemocytoblast of the embryologist by the megaloblast of the haematologist in this setting.

In the diagram by Dr. M. L. Thomson (Aug. 15, p. 198), in which he presents schematically Israels's idea of red blood cell development, it will be seen that while the megaloblast is placed in a separate lineage from the normoblast, it is shown as ripening into the macrocyte, not the obvious megalocyte, to me a quite unintelligible procedure. It will be difficult, further, to justify the addition of the term "proerythroblast" (in place of the commonly employed "haemocytoblast") to the already overloaded and confused nomenclature. Again no distinction is drawn between primitive and definitive haemocytoblasts (proerythroblasts), with the result that, while the megaloblast has indeed been relegated to a separate lineage, the whole confusion arising from the idea that megaloblasts can develop into normoblasts still persists, the difficulty being merely shifted one stage backwards. Finally, while it may be supposed that the term "erythrocyte" in the diagram is really intended for "normocyte" I am unaware of any justification for the suggestion that the normoblast develops into the macrocyte.

Davidson, Davis, and Innes (July 11, p. 31) supply no evidence that the preponderant cell in the marrow of their cases is the megaloblast; and before the title of their paper can be justified it will have to be shown also that the condition they are dealing with is one concerned not with macroblasts and macrocytes but with megaloblasts and megalocytes. The facts are all against the possibility of this being realized.

Several other points, such as the function and fate of the megacaryocyte, the inner significance of anisocytosis with the simultaneous presence of megalocytes and microcytes, and the part played by deficit of liver agent in megalocytic and macrocytic anaemias respectively, could be elaborated, but as these have already been discussed elsewhere and are at present being dealt with again in an article in the Press, there is no necessity to consider them here.

—I am, etc.,

Aberdeen J. P. MCGOWAN.

SIR,—The article by Prof. L. S. P. Davidson, Dr. L. J. Davis, and Dr. James Innes (July 11, p. 31) is of great value to the obstetrician, as up to the present time few such thorough clinical investigations on that subject have been carried out. In 1931 I published one of the first follow-up cases of pernicious anaemia of pregnancy (*Zbl. Gynäk.*, 1931, No. 23, referred to in DeLee's *Principles and Practice of Obstetrics*, 1938). The case was that of a 25-year-old primipara, who was admitted to our clinic as a case of pre-eclampsia in labour. According to the history, the patient was well up to the third month. She then became pale and complained of dyspnoea on exertion, palpitations, dizziness. In the 10 days before admission she developed oedema of the ankles, headaches, and great weakness. The general examination of the very dyspnoeic patient made one think first of a decompensated mitral failure. The second stage of labour had to be shortened by forceps, followed by intravenous Ringer's drip infusion in view of the appearance of shock. Her condition improved. Urine: albumin+++, urobilinogen+++; stools: urobilinogen +++. The routine clinical examination after the confinement and the complete blood count showed most of the outstanding features of pernicious anaemia of pregnancy: R.B.C. 1,800,000, Hb 37%, colour index 1.02, W.B.C. 4,200, anisocytosis, macrocytosis, ovalocytosis, reticulocytes 110%. Under systematic liver therapy the patient was completely cured within four weeks and remained so, as the later post-natal examinations showed.

Such a case is important from the clinical point of view as many anaemic patients are often admitted to hospitals as cases of "toxaemia" or "congestive heart failure." It shows the need for early recognition of Aubertin's classical triad, "anaemia—dyspnoea—oedema," in routine ante-natal examinations, and, as the Edinburgh authors particularly emphasize, peripheral blood pictures and sternal marrow examinations in suspicious cases of anaemia in pregnancy. Labour brings about acute exacerbation of anaemia, which is the reason why early blood transfusions with vigorous haematinic treatment should be carried out after the diagnosis has been made.

The authors' proposal to replace the old-fashioned term "pernicious anaemia of pregnancy" by "megaloblastic anaemia of pregnancy" is certainly scientifically justified. The thorough differentiation of this type of anaemia from the cryptogenetic Addisonian–Biermer pernicious anaemia in view of the temporary duration has been pleaded formerly by obstetricians (Heim, 1923, Oettingen, 1924, in their works on pregnancy and pernicious anaemia).—I am, etc.,

Surrey County Hospital, Kingston-on-Thames WALTER SPITZER.

Treatment of Haemophilia

Sir,—Though the letter from Dr. R. G. Macfarlane and Prof. L. J. Witts (Aug. 1, p. 140) is most opportune in pointing the way to the management of haemophilia, it is necessary to admit that in this disease continued haemorrhage, even if slight, is a matter for serious concern and a source of great anxiety. The arrest of the bleeding at the site is an important part of the treatment and may be an urgent problem, and it is necessary to consider those measures which are ready to hand and can easily be applied. In the case which has led to this discussion it would appear that the bleeding was not arrested but was merely deviated, hence the extravasation into the tissues of the floor of the mouth and the fatal result. The course of events in this case emphasizes that, whatever measures are employed, it is essential that the bleeding should be arrested and not merely obscured. In order to bring this about in haemophilia some reliable haemostatic preparation must be brought into intimate contact with the bleeding area, and to accomplish this it is necessary to remove clots, debris, or soft oedematous granulations if they have had time to spring up. In my experience ordinary turpentine is an excellent haemostatic provided it is properly used. In the *Lancet* for July 31, 1915, I drew attention to the value of turpentine as a haemostatic, and was subsequently reminded by a correspondent that Billroth had extolled its virtues in his *Surgical Pathology and Therapeutics* (New Sydenham Society, 1877).

In dealing with a tooth socket the matter is quite straightforward. Under a good light the socket must be swabbed out until it is empty and as dry as the oozing will allow. A small strand of gauze or a strip of lint which has been soaked in turpentine and firmly squeezed out is then packed firmly into the socket. Any excess is cut off, and a small piece of folded dry lint or gauze is placed on top of the packed socket in order that it may soak up any excess of turpentine. It is only necessary to keep this pad in position for an hour or two. A conscious and intelligent patient may be able to hold it in position with the finger, thus exercising useful pressure; in other circumstances a rather bigger piece may be used and the jaws may be bandaged together, so that in this way the pad is kept in position and pressure is exercised. In about four days the socket plug will be found to be loosened by a slimy discharge, which follows the use of turpentine, thus enabling the plug to be easily withdrawn and without recurrence of bleeding. If, in the process of removing the plug, there should happen to be the slightest sign of recurrent haemorrhage the surgeon must be content to cut away that part of the plug which has already been loosened and the remainder must be left in position for another day or two. One other word of caution is necessary. The number of pledgets of lint or gauze must be carefully counted and recorded, for I have known a persistent sinus develop into the mouth as the result of a plug of this sort which was overlooked and left *in situ.*

I have used this plan in several cases of bleeding in haemophiliacs, not only from tooth sockets but from other situations, and with unvaried success. I therefore feel that I can recommend it as being convenient and efficient if properly used. Haemostatics like Russell's viper venom and some other preparations are stated to be very efficient, but they are not always readily obtainable, whereas turpentine is almost invariably to be had. Of course in these days the measures for the control of the haemophilic state will also be employed.—I am, etc.,

London, W 12 G Grey Turner.

Social Medicine

Sir,—We all welcome the establishment of a chair of social medicine as we welcome any new institution based on an ideal, but I trust that laymen who may chance to read recent letters on the subject will not get the idea that somehow the clinician or the laboratory worker has been to blame for the neglect of the subject hitherto. The profession has aways had those with ideals and willing to spend their energies freely in the public good. For example, the profession cannot be held responsible for the present state of affairs in regard to diphtheria, industrial fatigue, and tuberculosis. It surely ought not to be necessary for the Chief Medical Officer of the Ministry of Health to have to appeal to the public regarding immunization against diphtheria. Why it is not made compulsory only the politicians know, and meantime hundreds of children die annually from the disease!

In the same number of the *Journal* in which the new chair was announced (July 25) Dr. H. M. Vernon (p. 108) is reported as deploring the neglect of the investigations made during the last war in regard to industrial fatigue—made by official bodies at public expense. All who know anything of the subject are agreed that the application of many of the published findings would not only improve the health of the workers but would greatly increase our war output. Under the present wasteful system, which is responsible for the loss of millions of working hours, the workers, however, get more money, and the employers do not complain as it would otherwise go on the excess profits tax. We must not, however, decry this tax too much, for it is agreed that it has been chiefly responsible for the greatly increased facilities now given to medical officers. Many of the Government Departments are staffed by individuals so exhausted that they cannot be expected to administer as they ought and many are too tired to realize it. Increasing sick-leave will soon take its toll of those who really work hard too continuously.

With regard to tuberculosis the problem is more complex, but again is not so much one for the doctor as for the administrator and the public. Even if we could diagnose every case of tuberculosis in the country, what further could be done without a great change in the public attitude to the subject? It is too commonly forgotten that the young person who may feel quite well does not wish to be labelled tuberculous, while many a man with a positive sputum lives an effective life (and disseminates the disease presumably) for more than 20 years.

A first step in social medicine is the proper education of the public towards preventable disease, and we might begin in the universities, which ought to be the leaders of thought. There are still too many so-called educated people in the community who fail to recognize that a properly planned society, which is so essential in our overcrowded island, is impossible unless those who guide public opinion know more of the essential scientific facts upon which such a society must depend. All university students ought to have a compulsory course of social science, which would include instruction in the maintenance of health.

We must beware lest the new social medicine be relegated to the same academic obscurity as sociology or involved in party politics, for its recommendations will often run contrary to individual freedom. Let us hope that the new institution will not be another body crying in the wilderness, but will be a real source of inspiration to the public conscience.—I am, etc.,

King's College, London R. J. S. McDowall.

Trichlorethylene as a General Anaesthetic

Sir,—I was interested in the letter by Drs. K. G. Lloyd-Williams and D. Hewspear (Aug. 8, p. 170) describing temporary auricular fibrillation in a patient undergoing partial thyroidectomy under trichlorethylene anaesthesia. It is, of course, possible that the fibrillation was due to trichlorethylene, although up to the present electrocardiograms have shown that arrhythmias under this anaesthetic are usually caused by either auricular or ventricular extrasystoles. There are, however, two other factors in this particular case which seem to me more likely to have caused the condition

In the first place, the arrhythmia was first noticed "*immediately after intubation.*" Temporary arrhythmias quite commonly follow intubation, and this is one of the reasons why I abandoned endotracheal anaesthesia as a routine for unobstructed goitre operations. A considerable amount of work has been done on this subject, and it has been shown (Reid, L. C., and Brace, D. E., *Surg. Gynec. Obstet.*, 1940, **70**, 157) that arrhythmias are most likely to occur if intubation is performed under light anaesthesia and if the premedication includes morphine or one of its derivatives. The condition appears to be reflex in origin.

The second factor is adrenaline, which was used in the high concentration of 1 in 150,000. For many years I was accustomed to infiltrations of 0.5% novocain and 1 in 250,000 adrenaline, although tachycardia and arrhythmias followed fairly frequently. On one occasion fatal primary cardiac failure, probably ventricular fibrillation, occurred immediately after infiltration. I then tried reducing the adrenaline concentration, but found that the vasoconstriction became unsatisfactory.

Eventually, after a latent period of nearly 20 years, it slowly dawned on me that if the patient was anaesthetized with nitrous oxide and oxygen, the novocain not only performed no useful function, but was actually a nuisance, in that its vasodilator effect counteracted the adrenaline. On omitting the novocain, the adrenaline can be reduced to 1 in 500,000 in normal saline. If this solution is used for infiltration at least 20 minutes before the surgeon makes his incision, a practically bloodless field results, and I have never seen either tachycardia or arrhythmias result.

From the reasons given above I think it doubtful whether trichlorethylene itself caused fibrillation in this specific case, but at the same time our knowledge of the effects of the drug upon the cardiovascular system in man is far from complete and the publication of any additional data is valuable.—I am, etc.,

St. Albans, Herts C. LANGTON HEWER.

The Medical Curriculum

SIR,—The writer of the leading article under this heading (Aug. 15, p. 191) makes a number of statements which are at variance with the facts as regards both the final examination and medical education, at any rate in a progressive teaching hospital. If this was simply the expression of an individual opinion it would be of small consequence, but when published as a leading article in your *Journal* it has a different significance. From what the writer says it would seem that he has but slight acquaintance either with the final examinations or with the modern methods of medical education. He speaks of "bizarre cases," which he imagines are hunted up with great difficulty for the purposes of the final examination and then disappear either until the next examination or death claims them.

From an extensive personal experience as an examiner in medicine for the Conjoint Board, the Universities of Oxford and London, and the membership of the Royal College of Physicians, I can say that his statement with regard to the final examinations in medicine is quite erroneous. "Bizarre cases" are not wanted for final clinical examinations, and there is no difficulty whatever under peacetime conditions in finding any number of suitable patients from the ordinary hospital clientele. Under war conditions suitable cases can be found without difficulty in the sector hospitals.

With regard to clinical education, the writer suggests that the methods now in vogue differ hardly at all from the method of "walking the hospitals" as practised, I suppose, some 60 or more years ago. What a travesty of the truth! He speaks of an alternative in "the scientific or physiological approach for which many teachers hanker." Inferentially one must assume that this method is forbidden. But in my experience it is the one at present in vogue in any modern and progressive medical school. Surely, sir, if the teachers hanker for this method all they have to do is to employ it. I do not understand what the "synthetic method" may be, but if, as I suspect, it means spoonfeeding, it is surely to be deprecated. There are few who would not agree that the curriculum needs revision and that the scheme of medical education could be improved, but do not let us discard what is good in the existing order of things simply for the sake of something new and call the result progress. The writer, for instance, seems to think that clinical clerkships are to be deprecated, but surely the investigation of the patient by the student at the bedside is one of the most essential aspects of medical education.

I should like to end on a note of complete agreement with the writer when he says with regard to pre-clinical teaching that it is not clear why so little time is left for the study of the mind. The reason for this, and its cure, lie largely with the anatomists and physiologists. There are signs, however, that they are becoming conscious of the need for a thorough revision of the teaching of their subjects.—I am, etc.,

London, W 1. C. M. HINDS-HOWELL.

SIR,—Referring to your leading article on the medical curriculum (Aug. 15, p. 191), I think that the emphasis laid on the division of the curriculum into pre-clinical and clinical is unfortunate. The division is perhaps convenient in many ways, but it is wholly artificial and educationally unsound. It has done much to obscure for students the importance of scientific methods in medicine by the implication that once the official examinations in anatomy and physiology are passed there must be developed a new outlook and a new technique which comprise the mystical "art" of medicine. It has also set up a barrier against that close co-operation between anatomists, physiologists, and clinicians which is so essential in any sound scheme of medical education. The intelligent study of medicine is based on the application of principles common to anatomy, physiology, pathology, and ancillary subjects. Anatomy and physiology must continue to be taught after a student has begun hospital work, not as applied anatomy or applied physiology (as though the earlier work had no application to medicine), but as a natural continuation of the subjects.

Your article states: "It is also clear that life is too short for the medical student to learn everything from the fundamental or scientific standpoint, and it seems probable that he will have to get his scientific education and background in his pre-clinical years and devote the clinical years to the acquisition of technical skill." If this is accepted there seems to be no need for a "pre-clinical" period; let us revert at once to a complete system of apprenticeship so that more time may be available for the acquisition of these "technical skills" which appear to have no relationship to scientific method.

There can be no satisfactory advance in medical education until the curriculum is reviewed as a whole, and the teaching in different departments is correlated so that the student may see, so far as present-day knowledge will allow, a logical application of fundamental principles in the presentation of clinical work.—I am, etc.,

Faculty of Medicine
The University, Sheffield, 1. G. A. CLARK.

Urethral Instrumentation

SIR,—Both Mr. Clifford Morson (June 20, p. 771) and I (July 4, p. 25) were led by our own observations to deplore the ill results that follow upon inexpert treatment of cases of retention of urine. Mr. Morson proposed as a remedy more efficient training in the operation of passing a catheter, whereas I suggested that, as more than the operation itself was involved in the treatment of these cases, the patient should be regarded as an emergency and admitted to an institution.

Dr. Vincent Norman replied to my suggestion by minimizing the dangers of catheterization in the patient's home, and by stating that practitioners were fully aware of these dangers and accordingly took precautions against them. His arguments about the difficulty of admission to an institution at 3 a.m. do not, I am sure, hold with regard to a perforated peptic ulcer, and, therefore, should not apply to acute retention. I am prepared to admit that many institutions do not welcome these cases, and the fault lies often with the surgical staff; but then I am not out to attack practitioners but to find the best method of treatment of these patients. I am not a one-specialty man, and the remainder of his letter is thus irrelevant.

I could quote a number of cases illustrating how justified I was in my complaint, but will, for space reasons, cite the most significant one. A patient two years previously had had retention relieved by catheterization; his relief was great and his gratitude very real; he was not encouraged to have an operation. I saw him recently with chronic retention and a blood urea of 300 mg.%. He was probably a fit, healthy man with little renal damage when he developed retention previously. He was catheterized successfully in every way; in fact so excellent was this treatment that he was afterwards able to pass his water freely. Unfortunately the prostate continued to enlarge, and when admitted he was near to dying from uraemia. I should like to hear some opinions of the percentage of patients with retention who, after catheterization, pass their water freely, and have no more serious trouble beyond the slight prostatic symptoms so commonly met with in elderly men. In my experience a man who has developed retention will almost certainly require further treatment later.

I regard acute retention as almost an absolute indication for operation, in the same way that an attack of appendicitis is an indication for appendicectomy either then or later in a quiescent phase. If this is so, then the sooner operation is performed the better; these patients are getting older, and their kidneys are being progressively damaged. Catheterization then becomes a pre-operative treatment, and the surgeon should be permitted to express his views on how it should be carried out. In the *Collected Papers of the Mayo Clinic*, 1940, there is a report of 1,000 perurethral operations with a mortality of under 1%. The average age of the patients was 70, and 43 of them were over 80. On these figures Dr. Atkinson will agree that one should not too readily assume that a patient is too old for surgical treatment.

In brief, the ideal procedure should be to transfer the patient as rapidly as possible to hospital after having given a dose of morphine. There he should, after shaving, be catheterized with a rubber or silk web instrument with full aseptic technique, preferably in the theatre; the bladder should be decompressed gradually and then allowed to drain through a tied-in catheter. A house-officer dealing with one or more of these cases every week can be trained by the surgeon to carry out the manœuvre efficiently. In remote parts of the country such a plan may not be possible, and then I would agree that catheterization may become necessary. I would suggest that not more than 1 pint should be withdrawn and admission to an institution then arranged during the following 6 hours.—I am, etc.,

Reading GORDON L. BOHN.

Jung's Psychology

SIR,—Your sympathetic review of Dr. Jacoby's book *The Psychology of C. G. Jung* makes the following statement: "Jung does not in any way refer theoretical 'structure and function' of the psyche to the structure and function of the body; consequently [1] in some ways his teaching is more of a religion than a science, and is said to have wider application than 'medical healing.'" This, I think, requires comment, because it might well in certain circles damage the reputation of the medical psychologist who uses Jung's method in his work.

In the first place it is not true to say that Jung does not relate mental to physical structure and function. I may quote in this connexion an article published in your *Journal* in, I think, 1938, in which a report of a dream sent to him is quoted giving a diagnosis of organic disease in a particular part of the brain. I may also refer to a similar diagnosis in *Modern Man in Search of a Soul.* Other references will be found in *Contributions to Analytical Psychology,* while one of his followers, Prof. Heyer, has dealt with the gastric neurosis in his book *Organism of the Mind.*

It remains true, however, that analytical psychology is firmly based on the psychological standpoint, but there is no reason to think that Jung's work has produced something that is even "in some ways . . . more a religion than a science." Jung is simply a student of human nature, and his work is neither more nor less scientific than that of others who are interested in the same subject. It should be realized that Jung has created not a branch of medical psychology but a new method of studying the unconscious process, and it is only one aspect of his work that is concerned with psychotherapy. This is why analytical psychology has a "wider application than medical healing." He has investigated "normal" as well as "pathological" phenomena. In the course of his researches Jung came across essentially religious phenomena, but he has never gone beyond the strictly scientific standpoint of recording and classifying the phenomena which he has observed. He has no more created a religion than have the anthropologists.

The sort of mistake which is contained in your review may, to a certain extent, be laid at Jung's door, for his writings often presuppose a knowledge which only a few people possess. Conceivably he should be more elementary, but it is really the task of analytical psychologists to fill in the gaps which he leaves.—I am, etc.,

Nottingham. MICHAEL FORDHAM.

Scabies

SIR,—Dr. A. M. H. Gray (Aug. 8, p. 170) comments on the rarity of scrotal dermatitis as a complication of the treatment of scabies by benzyl benzoate. Approximately 8,845 persons have received this treatment at the Birmingham Public Health Department's scabies treatment centres during the past 18 months (6,413 by the spirit soap lotion and the rest by the *National War Formulary* emulsion). One case of scrotal dermatitis has been reported, and in this case the patient had followed up his benzyl benzoate treatment with a couple of hot strong lysol baths. The interest of this case lies in the fact that, had I not been able to see the patient personally and so learn the whole story, the dermatitis must necessarily have been attributed to the benzyl benzoate.

Dr. Gray mentions that the treatment cannot be carried out by the patient himself. This is often said; I wonder why. Surely there is one, and only one, essential requirement—that the emulsion should be applied to every part of the patient's skin (face and scalp excepted, of course). I should have thought that an intelligent patient, anxious to be cured, was perfectly capable of doing this. In fact it seems likely that the patient might be more thorough in the treatment of, say, his genitals (an important site of infection in the male patient) than would a trained attendant. I am not advocating self-treatment as a routine; my point is that success in treatment is proportional to the care with which the benzyl benzoate is applied, whether by attendant or by patient, and accordingly it is a method well suited to use by the intelligent patient in his own home under medical guidance.—I am, etc.,

Birmingham L. J. BACON.

SIR,—Your leading article (July 11, p. 44) should help to rouse the medical profession to attack the problem of scabies with a greater measure of success. For 250 years we have sheltered behind impressions and beliefs rather than facts. Surely this is why you find it "remarkable that scabies should be so difficult to control." We are often unable to trace the source of an infection; we are not sure of the length of the latent period before symptoms occur; we may be unable to confirm our diagnosis; and we cannot be certain that viable mites do not remain after treatment.

You rightly draw attention to the carrier or latent case who harbours live mites without rash or irritation. I do not, however, consider such persons alone to be insensitive to the parasite, as experiments with live mites burrowing and crawling on the skin lead me to seek some cause for the irritation other than the progress of the mites through the skin.

You refer to the need for suspecting vesicles near the hands or feet. For 6 months I examined the contents of vesicles in vain, until it was explained to me that the burrow, however short, lay in the cuticle superficial to the vesicle, and that the vesicle was deep to the entrance rather than to the active blind end of the longer burrows. There is evidence that this confusion between burrows and vesicles often leads to disappointing results in the search for the acarus and to errors in diagnosis in atypical cases.

Dr. Kenneth Mellanby, Major C. G. Johnson, and Mr. W. C. Bartley (July 4, p. 1) find that benzyl benzoate lotion with soft soap and spirit is effective in the treatment of scabies, but you mention this as the only sarcopticide to be compared with sulphur ointment. The dermatitis sometimes caused by this lotion does not occur when benzyl benzoate is employed as an aqueous emulsion with wax, or as a simple solution in spirit.

I agree that an increased accuracy of diagnosis is essential, though I believe that such an advance will only follow a keener interest in and search for the parasite. I admit that in the Army our diagnosis may not always be above reproach, but I am not a little disappointed when, after confirming the diagnosis in a soldier, I find that his small child has been attending the local clinic for the past three months with a "teething rash," and that his wife has irritating spots on her wrists and fingers which her doctor attributes to the new national flour.—I am, etc,

H. F. LUNN,
Captain, R.A.M.C.

Tietze's Disease

SIR,—Following the article on Tietze's disease by Drs. A. Morton Gill, R. Arden Jones, and L. Pollak (Aug. 8, p. 155) the following case may be of interest. In this instance the pain and swelling of the cartilages appear directly to have preceded an attack of pleurisy.

The patient, a labourer aged 35, was admitted to Guy's Hospital on July 5, 1942, complaining that 10 days previously he started getting pain over the right side of the sternum together with dyspnoea and inability to bring up sputum. He went to bed and 2 days later noticed a swelling developing just to the right of the sternum. On the 4th day he began to get pain in the left axilla over the 7th and 8th ribs. This second pain was pleuritic in nature. A few days after admission a doubtful rub was heard in the left axilla. Previous illnesses: chronic bronchitis many years; about 3 attacks of asthma each winter. No family history of tuberculosis.

On July 23 he was transferred to a war hospital. He is still somewhat short of breath, but the pleurisy has subsided. He complains of an aching pain on the right of the sternum which is made much worse by deep breathing. He is a lean man with sallow complexion; intelligent; all finger-nails are nibbled to the moons. Blood pressure 130/90. Mouth, some pyorrhoea. Chest movement, largely up and down. Poor air entry with scattered low-pitched rhonchi. Very tender over the right 4th, 5th, and 6th costal cartilages, which are slightly swollen and the interspaces almost obliterated. The swellings feel hard and are discrete from the skin. Springing of the ribs causes sharp pain over the affected area. Other systems normal. Blood sedimentation rate 9 mm. in first hour. Kahn reaction negative. *X*-ray examination of chest showed increased fibrosis with large roots and fibrosis at the right apex. Sputum: no tubercle bacilli seen on direct smear. Radiograph of costal cartilages: no abnormality noted.

The patient still has constant aching pain over the right side of the sternum (Aug. 10, 1942) which is less severe than formerly and the area is no longer tender. The swellings are, however, no smaller than on admission.

I am indebted to Dr. Hale White for permission to report this case.

—I am, etc.,

P. R. C. EVANS.

Hyperostosis Frontalis Interna

SIR,—I hope that I am not being unduly dense and becoming mixed up in my nomenclature, but does not Dr. C. T. Andrews, in his article on hyperostosis frontalis interna (Aug. 15, p. 185), mean to write "lowered" rather than "raised" glucose tolerance? His patient had a fasting blood sugar of 150 mg. per 100 c.cm., high blood sugar values for the next two and a half hours, and glycosuria on 3 days out of 4. She had also been previously diagnosed as diabetic, presumably after the discovery of a lowered sugar tolerance curve.

Russell Brain (1935, "Glycosuria in Cerebral Lesions," read before the Society of British Neurological Surgery; unpublished) points out that hypothalamic lesions may give glycosuria with or without hyperglycaemia. Hypopituitarism, on the other hand, is said to give a raised sugar tolerance. If we are to assume that the symptoms in Dr. Andrews's case are due to hypothalamic damage, then I, personally, should expect to find glycosuria with or without hyperglycaemia and a lowered sugar tolerance. If I am being dense I apologize, but I should be grateful if the point can be cleared up.—I am, etc.,

Caterham, Surrey. J. MACKAY CRAWFORD.

Enteritis associated with Giardia lamblia

SIR,—The article by Drs. G. Ormiston and Joan Taylor and Prof. G. S. Wilson on enteritis associated with *Giardia lamblia* (Aug. 8, p. 151) will, I trust, be remembered when dealing with enteritis of apparent unknown cause. I have had some experience of this parasite when in the Middle East, and believe it to be commoner than many realize; it is possibly the cause of outbreaks of unexplained enteritis, particularly in institutions and where there is apt to be overcrowding.

I would like to mention a few points in connexion with *Giardia lamblia* which were not brought out in the article and which may help in investigating cases. (1) *Giardia* are found in cats, mice, rats, and some human beings are possibly carriers. They are usually found in the upper part of the small intestine, in the gall-bladder, and in the biliary system. (2) The best way to isolate the protozoon is by means of duodenal drainage through the standard Ryle's tube. This enables the parasite to be seen free from lower intestinal contamination. By injecting a small quantity of magnesium sulphate through the tube the gall-bladder can be drained. The yellow colour of the bile acts as a good contrast background to the parasite. (3) Apart from acute intermittent and chronic enteritis, cases of acute cholecystitis have been reported from time to time, which have been due to *Giardia lamblia*. (4) I have known 3 cases of acute catarrhal jaundice to be associated with heavy infection by *Giardia lamblia*. Two of these cleared up quickly with the treatment and disappearance of the parasite. The third proved fatal, and microscopical examination of the liver showed a heavy infection of the biliary system with protozoon.

In view of present wartime conditions, when there is an unfortunate overcrowding both in and out of the Services, with, in some instances, faulty sanitary conditions, an increase in the number of natural hosts, and a possible increase in the dissemination of the parasite, I would like to congratulate the authors on reminding us in their interesting article of the existence of this parasite.—I am, etc.,

Bromsgrove. J. A. SMITH.

Treatment of Malaria

SIR,—I have read with great interest Prof. Warrington Yorke's article on the diagnosis and treatment of malaria in England (July 18, p. 61) and Dr. E. S. Fennell's suggested intravenous method (Aug. 8, p. 171). Having worked on malaria for a number of years in the Tropics, sometimes in hyperendemic areas, and having experience of the disease in its worst forms, may I take the liberty of making a few comments on its diagnosis and treatment?

There is one algid type of malaria which Prof. Yorke has overlooked and which I have quite frequently encountered during an epidemic—the "allergic type." The symptoms in this type are severe headache, vomiting, diarrhoea (sometimes containing blood), subnormal body temperature with a high rectal temperature, and general urticaria. Blood smears showed multiple infections of R.B.C. with malignant tertian rings. Quinine per os was out of the question, so I decided to give it intravenously. I am herewith giving a résumé of my article published in the *Indian Medical Gazette*, 1926, on "Intravenous Use of Quinine, Arsenic, and Adrenaline in Algid Cases of Malaria." I have given a total of about 3,000 to 4,000 injections without a fatal case.

Technique.—Quinine, specific for malaria; arsenic, a haematinic and general tonic in small doses; adrenaline counteracts fall of blood pressure due to quinine and "quinism." 10 grains of quinine bihydrochloride is dissolved in 20 c.cm. of redistilled water in a test-tube, to which is added 3 drops of liq. arsenii hydrochlor. The tube is then heated over a spirit lamp until the quinine is completely dissolved. Allow the sol to cool to about body temperature, draw up 10 minims of a fresh sol of liq. adrenalin. hydrochlor. into the syringe containing the quinine sol and inject, preferably into the median basilic vein at the bend of the elbow.

Do not heat the adrenaline, as it decomposes on heating and will not have the desired effect. The injection must be made very slowly, at least 7 to 10 minutes. If too rapid an injection is made it might cause acute dilatation of the heart and syncope. The rate can be judged by the patient's respiration. If the injection is made too fast the patient will complain of a tight feeling in the chest and his respiration will get hurried. I found the best time to give the injection was when the patient commenced a rigor, as the sporozoites at this stage are free in the general circulation, and this offers an opportune moment to destroy them. My results have been verified by blood examination before and after injection, by which I found that if an injection is given at this stage there is a marked reduction of the parasites. The following mixture was given when the patient was able to swallow:

℞ Quinin. sulph.	gr. x
Acid. citric.	gr x
Tr. nuc. vom.	♏x
Liq. arsenicalis	♏iii
Aq. syrup. limon.	ʒj
Aq.	ad ℥ss

℥ss t.d.s. for 10 days.

A diet which favours blood regeneration should be given, such as red meat, green vegetables, fruit (vitamin C), plenty of fluid with glucose if vomiting is persistent The anaemia following malaria is of a microcytic type, as with most protozoal infections, and iron is indicated.

The synthetic compound of atebrin could be used instead of quinine, as advised by Prof. Warrington Yorke, after the acute stage has subsided.

—I am, etc.,

Whitchurch, Cardiff SYDNEY J. BELLGARD.

SIR,—I was interested in the report of a meeting of the Royal Society of Tropical Medicine (Aug. 8, p. 167) at which the treatment of malaria was discussed. I agree with Prof. Warrington Yorke that the conservation of the present limited supply of quinine must be effected by rigid economy in the large amount used for prophylactic treatment. I admit to some bias, as I have never believed in the efficacy of the daily 5 grains as a prophylactic. About 40 years ago in India and Burma I treated severe cases of malaria by intramuscular injection of quinine bihydrochloride, and never saw the slightest ill effect from it. On the contrary, I am convinced that it saved lives.

In 1906, when serving in "the bush," Sierra Leone Protectorate, I contracted malignant tertian malaria confirmed by myself by microscope. As no other doctor was available I treated myself by intramuscular injections of quinine bihydrochloride. Except for a mild recurrence, also treated by injection (single), ? two months later, I have never suffered from malaria since. I am therefore in full accord with Prof. Yorke in expressing "surprise and consternation" at Sir R. Christophers's denunciation of the intramuscular use of quinine.—I am, etc.,

Bath. J. COWAN, M.B.
Lieut.-Col., R.A.M.C. (ret.).

Treatment of Threadworms

SIR,—Prof. James Miller has pointed out to me Dr. C. Paget Lapage's letter (June 13, p. 738) on the treatment of threadworms, in which he advocates the use of barium. It is our experience that any mode of treatment for pinworm infections which depends on its mechanical effect alone is at best purely palliative. And while a number of worms may be dislodged by the use of barium, a few are bound to escape and will serve as the nucleus from which a new autoinfection is quickly built up.

Recent investigations have made available two drugs which are specific in the treatment of pinworms—gentian violet and phenothiazine. Gentian violet is administered in coated tablets, either enteric-coated or with a water-soluble coating of an adjusted thickness which disintegrates at a specified time after ingestion. The coated tablets are given to ensure their reaching well down the intestine before they disintegrate, thus providing a maximum concentration of the drug at the site of infection. Our tests with gentian violet in the treatment of pinworm infections in children of school age have shown it to be effective in 60 to 90% of those treated (Miller *et al.*, *Canad. med. Ass. J.*, 194, **43,** 455). The following doses are recommended: Children under 10 years, 1/4 grain 3 times a day before meals for 10 days; children from 10 to 13 years, 1/2 grain 3 times a day before meals for 10 days; children over 13 years and adults, 1 grain 3 times a day before meals for 10 days. These dosages are not rigidly fixed, and if a child is big for its age or is small and puny the dose is determined accordingly. We found that untoward symptoms were almost entirely avoided if the drug was given in 2 five-day periods separated by a treatment-free period of one day.

Phenothiazine administered in chocolate tablets is even more efficient than gentian violet in the treatment of pinworm infections (Miller and Allan, *Canad. med. Ass. J.*, 1942, **46,** 111). However, because of its haemolytic action and other toxic effects, we agree with Dr. Lapage that its use should be avoided until more is known of its action on the body.—I am, etc.,

Institute of Parasitology, Macdonald College,
McGill University, Quebec. MAX J. MILLER.

The Blood in Cancer

SIR,—The blood may be studied from so many aspects that research on its appearances in cancer should be restricted to certain specified lines. Dr. O. C. Gruner seems to attempt too much in his book reviewed in the *Journal* of Aug. 8 (p. 159), for the results of his many years of study seem more a maze with many blind alleys than a path to follow hopefully. His book claims to offer the surgeon and the radiotherapist just what they want most from some laboratory method: diagnostic confirmation of the presence or absence of cancer; in treated patients the likelihood or not of the completeness of cure; and an indicator of the phase of the periodicity of each case. (The last point Gruner has given in more detail in Fig. 5 in his paper in the *Canad. med. Ass. J.*, 1941, **44,** 256.) But over a year's trial of his methods has shown, to my regret, a value most apparent in the patients with a high grade of tumour activity—i.e., where such additional tests are least needed.

Your reviewer states that Dr. Gruner "does not claim absolute certainty of diagnosis" by his methods, but such a claim would seem to be made on p. 41 for what are called "geniculate" mitochondrial forms in monocytes. These are said to be so pathognomonic "that if one genuine one is seen there is no need to search further to make the diagnosis." Further, as they "indicate active disease" (p. 64) the important conclusion is drawn that "more than half the cases treated by modern methods still show evidences of cancer in the body."

My studies (in progress) show these forms are not "pathognomonic," for similar forms are to be seen in the other leucocytes and in lymphocytes (more so in leukaemic blood); they are also to be seen in cancer and normal and non-cancer blood when stained (fresh blood) with Duboscq's solution or (dried films) with Victoria blue or with Morosow's silver method, and examined with a low condenser and good light (and binocular); they are also to be seen in many haematoxylin-stained tumour and normal cells; and (in very fine types) in viruses, as vaccinia, herpes, and molluscum contagiosum. These zig-zag noded forms of cell-reticulum or mitochondria need much further research.—I am, etc.,

London, W 1 J. H. DOUGLAS WEBSTER.

Meningococcal Septicaemia resembling Malaria

SIR,—The case of meningococcal septicaemia resembling malaria reported by Major-Gen. Robert Priest (Aug. 1, p. 129) recalled a similar interesting case under my care last year. In his patient meningococcal septicaemia was apparently diagnosed confidently by Major-Gen. Priest on the occurrence of characteristic cutaneous eruptions, although no organism was isolated. In my patient there were no cutaneous signs, and organisms were finally recovered from the cerebrospinal fluid. The two cases appear complementary in providing a clinical picture of interest.

A boy of 15 was admitted for observation to the local isolation hospital during a small epidemic of paratyphoid B fever. For 6 days previously he had been feverish and confined to bed. Blood taken the day before admission showed agglutination to *B. paratyphosus* B at 1/30. On admission he was comfortable, afebrile, and no clinical abnormality could be discovered. Blood culture was sterile; examination of urine and faeces and subsequent Widal tests ruled out the possibility of paratyphoid fever. On the evening of the second day after admission he had a rigor with headache, vomiting, generalized pains, and temperature of 103.6° F. Eight hours later the temperature was normal. Three further similar attacks developed with a quartan rhythm as in Major-Gen. Priest's case. No cutaneous eruption developed. Several blood films revealed no malaria parasites, but a course of quinine bihydrochloride was given, and the next rise in temperature did not occur as expected, but recurred after four afebrile days when the patient was still receiving quinine. Owing to pressure on the accommodation and the necessity to admit patients requiring urgent treatment, he was transferred the next day for further investigation to the local general infirmary. Investigations there revealed no abnormality, and his temperature remained normal until his discharge a fortnight later.

Three weeks after discharge he was readmitted to the local isolation hospital suffering from severe headache and generalized pains of 3 days' duration. The diagnosis of meningococcal meningitis was confirmed by culture of the turbid cerebrospinal fluid. No rash was present. Treatment with sulphapyridine resulted in a rapid uncomplicated recovery. He stated that he had not really felt well after discharge from the infirmary.—I am, etc.,

Southport. F. E. CRAWLEY.

"Removal for Mental Observation"

SIR,—The article by Dr. Arthur Harris (Aug. 1, p. 136) is a timely contribution. It reveals a deficiency for which the general practitioner is not wholly responsible. Unfortunately Dr. Harris's remarks are too condensed to be of much practical value, and make little attempt at any substantial solution of the problem.

The average general practitioner has little time or opportunity to devote to the mental assessment factor. Academically he is usually poorly equipped for the purpose. What proficiency he may acquire has to be gained in the hard school of cumulative experience. Lately he has been granted the privilege of postgraduate study, but, in this, too little time has been allotted to the ever-growing importance of the abnormal mental state.

The general practitioner need not be too despondent about his mistakes. The senior specialist is still a long way from the acme of infallibility, which fact, no doubt, many of your readers have reason to deprecate.

Dr. Harris suggests that misdirected disposal may lead to public censure and may jeopardize prestige. Undoubtedly this is true, but is it not sometimes the outcome of diplomatic indiscretion on the part of an officious colleague?

Dr. Harris states also that all mental cases of "organic" origin should be lodged in a general hospital. The satisfactory operation of this policy would challenge even the ability of its author. At the present time I cannot visualize the general hospital that would accept without controversy any case with a dominant mental picture. The policy, however, does merit consideration. Would it not be practicable to institute an observation department in our general hospitals? If so, futile travel might be partly eliminated, patient and relative would probably be more co-operative, fuller investigation would be facilitated, and, incidentally, any anxiety on the part of the practitioner with regard to reputation would be appreciably relieved.

Too often has the general practitioner to sacrifice incentive and ability at the altar of inefficient and clumsy administration.—I am, etc.,

Birmingham. A. W. DOCKAR.

SIR,—I was interested to read Dr. Arthur Harris's article (Aug. 1, p. 136). He deals very thoroughly with the organic diseases that simulate acute psychoses by the presenting symptoms and signs of confusion and delirium, and the only additions I should like to make are cerebral contusion, hypoglycaemic states, and subarachnoid haemorrhage. I cannot, however, agree with his view that the majority of these conditions should not be admitted to the mental observation ward. These cases are unsuitable for home nursing and a source of worry, discomfort, and apprehension to other patients in the general wards. Moreover, in my experience, since the presenting symptomatology is one of mental abnormality and behaviour disorder there is little difficulty in explaining to relatives that in fact the observation ward is the ideal place for these patients, although their primary illness is physical.

The real pitfall in the management of these cases is their admission to a mental hospital under certificate, which can only be avoided by staffing the observation ward with efficient nurses and well-qualified doctors of sufficient experience to make a correct diagnosis. Under these conditions the observation ward forms an important part of the neuropsychiatric unit of any general hospital, and without it the hospital is unable to give the fullest service to the public and to the local general practitioners.—I am, etc.,

Central Middlesex Hospital, N.W.10. A. BARHAM CARTER.

A Depression–Hyposexual–Alopecia Syndrome

SIR,—I am grateful to Dr. Ucko (Aug. 8, p. 174) for his kind interest in our paper and agree with him that further investigations would have been helpful. They were omitted only because the case was actually under my care for a short time, and the patient was already being boarded-out when I first saw him. Moreover, perhaps Dr. Ucko does not realize that research in the hurly-burly of a war hospital is somewhat different from doing similar work comfortably in the West End. We pointed out the similarity of the condition we described to some aspects of Simmonds's disease, but we cannot accept that it is merely an undeveloped form of this illness. Simmonds's disease is characterized by emaciation, anorexia, asthenia, precocious ageing, breaking of the nails, hypotension, etc. None of these conditions was found to be present. Again, myxoedema shows swelling of the subcutaneous tissue, puffiness of the face, changes in skin coloration and texture, vocalization, gait, mentation, reaction to cold, etc. These were entirely absent. It does not appear to me that the malady which we have described is a variety of either hypothyroidism, however masked, or of Simmonds's disease, and had Dr. Ucko seen the patient I am sure that he would have agreed. Nevertheless, I hope that I shall have the good fortune to encounter further cases which will be under my care for a longer period, and I shall be able to repay Dr. Ucko's kind interest by conclusive proof that this is a new endocrine and psychiatric syndrome.—I am, etc.,

CLIFFORD ALLEN.

Body Mechanics

SIR,—A review in your issue of July 25 (p. 99) of *Body Mechanics in Health and Disease* by Goldthwait and others called forth a comment from Dr. George Macdonald (Aug. 8, p. 173) that the theories advanced in the book in question are similar to those propounded by Still, the original osteopath, 80 years ago. I must point out that long before this the theories had been propounded by the Swede P. H. Ling (1776–1839), on which he based his educational gymnastics for the acquisition and maintenance of health and his medical gymnastics for the alleviation and cure of diseased conditions.

It is unfortunate that osteopaths should so often arrogate to themselves "discoveries" to which they are not entitled. I may, for instance, mention that an article of mine, written in conjunction with Dr. Kellgren-Cyriax, on the manual treatment of the abdominal sympathetic (*N.Y. med. J.*, 1910, **7**, 193) was severely criticized by Smith in the *Lancet-Clinic* for 1911, who accused us of borrowing methods from the osteopaths and exploiting them as new. To this we replied in the former journal (1912, **95**, 897) by quoting a large number of authors of the Swedish school who had written about this method of treatment for many decades before the time of Still. Another example is to be found in the pretensions of osteopaths that it was they who discovered that vertebrae could be replaced by manipulation, and that this was a valuable measure in the treatment of spinal curvatures and various nervous troubles. They entirely ignore the fact that these methods were extensively practised by Dr. E. Harrison during the early part of last century, as can be seen from his papers on the subject in the *London Physical and Medical Journal* for 1820, the *Gazette of Practical Medicine*, and a number of larger works.—I am, etc.,

London, W 1. EDGAR CYRIAX, M.D.

Atypical Asphyxial Deaths

SIR,—I was interested in the short article on atypical asphyxial deaths by Dr. Norman Patterson (Aug. 15, p. 188). It is strange that three cases of distension of the pharynx with bread should have occurred in so short a time in the experience of one medical officer. This could obviously only happen in a mental hospital and in patients with a deranged mind.

Some ten years ago I was engaged in research on the lymphatic drainage through the oesophagus, and had as my subjects a series of monkeys on whom I passed an oesophagoscope. Naturally these tubes, being constructed for the human gullet, were over-sized for the monkeys and considerable anxiety was caused. Each time they passed the larynx and trachea the heart always stopped beating, even although the larynx had been anaesthetized with cocaine, and one monkey actually died under the operation. There can be little question that it was the pressure which caused the vagal inhibition of the heart, and I imagine that the cases described were of this nature rather than a true asphyxia.—I am, etc.,

Birmingham. MUSGRAVE WOODMAN.

Anaesthetic Death in the Surgery

SIR,—I would suggest to Dr. A. H. Bartley (Aug. 8, p. 170) that the dilemma he was involved in was due to an "error" in anaesthesia and would have occurred most probably in hospital also, given the same set of circumstances. Speaking as an anaesthetist, I strongly advise him to avoid chloroform or "ether–chloroform mixture" at all costs in cases of fracture and dislocation, as such patients are unusually prone to collapse under chloroform anaesthesia. It is also well known that shock is an absolute or relative contraindication to chloroform. I regard ether–chloroform mixture as essentially chloroform in action, and administer it with the same amount of caution as if it were pure chloroform, and only in those conditions for which a satisfactory reason for the choice of chloroform can be substantiated.

Though hospital is undoubtedly the better place for such a procedure, the risk of removal may be much greater than the relative advantage to be gained. For such a problem (increased in number many times by "blitzes") I have adopted, and intend to continue to adopt, either open ethyl chloride–ether sequence or gas-and-oxygen–ether sequence. Of the choice of two evils—"chloroform collapse" or risk of "post-operative pulmonary complications" (which, by the way, have occurred irrespective of the type of anaesthesia)—I prefer the latter. I have, I may add, witnessed both conditions.

If Dr. Bartley adopts this technique I feel sure he will not get another "nightmare," and should the worst occur this choice of anaesthetic will weigh much more in his favour than that of chloroform. The attendance of a colleague, wherever possible, is a *sine qua non.*—I am, etc.,

Bradford. P. Esmonde Woodroofe.

Sir,—The case described by Dr. A. H. Bartley is reminiscent of one of Guedel's illustrative cases in the chapter on ventricular fibrillation in his *Inhalation Anaesthesia* (New York, 1938).

Dr. Bartley says he reduced the fracture when the child was apparently under. One might infer from this that she was not necessarily really and truly sufficiently anaesthetized. Should this surmise be correct, and realizing the possible combined effect of pain, fear, and a chloroform mixture, "the stage would be well set for ventricular fibrillation" and, to continue the quotation from Guedel, the operation "provided the required added stimulus to produce the fibrillation. The fibrillation passed before anoxic depression rendered the heart unresponsive to its normal stimulus. It is doubtful whether the violent resuscitative measures influenced the outcome. Possibly the fibrillation passed in spite of the traumatic stimulation of the precordial massage."

My opinion is that the risk of inviting anaesthetic death in the surgery far outweighed the risk of added shock due to a journey of 7 miles to hospital. A further alternative was to secure the help of an anaesthetist.—I am, etc.,

Salisbury A. D. H. Simpson.

Sterilizing Sulphonamide Powders

Sir,—In connexion with the sterilization of sulphanilamide, may I, as a hospital pharmacist, be allowed to make a contribution to the *Journal.*

I have read with interest Mr. J. C. Cherry's letter (Aug. 1, p. 142) on the sterilization of dry powders and his method of sterilizing sulphanilamide. Messrs. May and Baker referred to the changes in colour which take place when sulphanilamide, sulphapyridine, and sulphathiazole are subjected to dry-heat temperature high enough to sterilize them (*Prevention and Treatment of Infection in Wounds by Sulphonamides,* March, 1941) and, as reported, the method probably turns the powders toxic. The only alternative method, therefore, is sterilization by moist heat.

I should like to comment upon one of Mr. Cherry's statements. He says, referring to his sterile powder: "The powder in the beaker may be slightly caked, and may need to be pounded a little with a glass rod." I think it is almost certain to be caked if a very necessary detail, omitted from Mr. Cherry's method, is not observed. Using a very similar method, I had, during my investigations into this problem, six out of six batches cake. If it is desired to make sulphanilamide cake or crystallize, the sure method is to allow moisture other than steam to get at it. Even if the powder is not moistened (as described in the last paragraph of Mr. Cherry's letter), water will still get at the powder and cause caking or crystallization. There seem to be two possible reasons for this, and I believe that one or both may be responsible for the difficulty. They are as follows and probably occur in this order.

1. When steam is turned on to the cold flask or other container and the cold powder, condensation takes place, water is formed, is heated during sterilization, dissolves the sulphanilamide, evaporates again as the powder gets hot, and leaves behind the powder it has dissolved in a crystalline form, usually as a solid cake. This should occur fairly early in the sterilization process. If it does, and if a fairly dense mass of powder is being sterilized—e.g., 15 grammes in a narrow container—steam may not have penetrated to the bottom of the mass before caking occurs. How is steam to penetrate the hard surface cake formed and sterilize the powder at the bottom or the centre?

2. Where a not too dense mass of powder is used (as in the case of 15 grammes distributed over the bottom of a flask, a relatively large area), steam gets at the centre of the powder before caking occurs, condenses, and cakes the core as well as the surface. Even if the core did not cake during sterilization, it would later when the powder mass cooled, because the steam in the centre would condense. It could not escape during the vacuum drying because of the hard outer cake. I am working to confirm these theories, but have proved that condensation of steam and formation of water are responsible for caking in methods where the dry powder is autoclaved.

If the powder can be sterilized in its final container, it is better than having to transfer sterile powder from one container to another, and there is then no need for sterile gloves, mask, and gown. I wish to describe a method of autoclaving sulphanilamide in its final container, whereby the sterilized preparation is available as a soft white powder suitable for insufflation. I completed my method early in July, and have since then done several test sterilizations of sulphanilamide, and in every case have produced a smooth white powder. In two different experiments the powder was deliberately contaminated, one with *Staph. aureus,* the other with *B. welchii.* Both powders were found to be sterile after autoclaving by my method as follows.

An autoclave with vacuum drying attachment (dressing sterilizer) was used and the container was a dry boiling-tube plugged with non-absorbent wool. The boiling-tube must be thoroughly dried, if possible in a hot-air oven. (1) The jacket pressure of the sterilizer should be ready at a pressure of 20 to 30 lb. (2) Allow steam at 20 lb. into the empty closed chamber of the autoclave and leave for five minutes. (3) Using the appropriate valves clear chamber of all steam and condensed water. This process has heated the chamber, and the boiling-tubes, loosely plugged with non-absorbent wool and containing the powder (in 5- or 10-gramme batches), are now placed in it. They should be placed on their sides, with the powder spread over their full length, giving a thinner mass for the steam to penetrate. (4) Leave the tubes for 15 minutes in the hot chamber; this heats tubes and contents sufficiently to prevent condensation inside and on the powder. (5) Autoclave at 15 lb. for half an hour. (6) Clear the chamber of steam and any condensed water quickly, and allow vacuum of 10 to 15 inches for 15 minutes. (7) Remove tubes from autoclave, place a tight sterile plug of non-absorbent wool on the top of the one already in, and cap tubes with a suitable paper—preferably cellophane. Caking does not occur. If apparent caking is observed, it is only present while the powder is still hot, and when cool a tap on the side of the tube is all that is necessary to show the sterile preparation to be the desired soft powder.

Thanks are due to Dr. Rosher, director, pathological laboratories, Mile End Hospital, where examination of the powder when contaminated and after sterilization was carried out, and to his assistants Mr. Crawley and Miss Brews; also to Mr. J. Leebody, medical superintendent of this hospital, for permission to carry out the work, and the medical officer of health, London County Council, for permission to publish. —I am, etc.,

St George-in-the-East Hospital, E.1 W. J. Buckland, Pharmacist.

Complacency in Anaesthetics?

Sir,—The letter from Dr. A. Mills (Aug. 8, p. 169) is so good that it seems to me important that where it contains doctrine which cannot be accepted by anaesthetists of experience equal in both giving anaesthetics and teaching to that of Dr. Mills this should be pointed out. Otherwise if passed unchallenged these fallacious statements might be accepted as correct by the comparatively inexperienced. Where I join issue with Dr. Mills is in (1) his implied condemnation of intravenous methods and (2) his contention that gas–oxygen–ether from a machine is not efficient for the deepest anaesthesia. Incidentally I may say that, like Dr. Mills, I have not seen a case of ether convulsion, but I do not attribute the cause of these to machines, because I know of many instances in which the convulsions have occurred when no machine was used.

Now as regards (1) Dr Mills's words are: "a drug can be introduced directly into the circulation to produce an *uncontrollable* state of coma, but this procedure does not appear to be a desirable one." This presumably rules out such methods as the use of pentothal intravenously. Dr. Mills's objection seems to me of theoretical value only. In practice it does not matter that the dose injected is uncontrollable because, guided by the knowledge gained through experiment and wide clinical practice, the anaesthetist puts in only so much of his anaesthetic drug as is certainly safe. This he does by injecting slowly, being guided by the symptoms evoked and by knowledge of the general limits of safety to which I have alluded. He has no need to control the dose after it is in the patient's body.

As regards (2), if it were true that satisfactory anaesthesia, say for upper abdominal operations, were not obtainable by gas-oxygen-ether, surely we should have heard of it from surgeons in no measured terms ere now. "The proof of the pudding is in the eating," and there are hundreds of surgeons working contentedly every day with an anaesthesia provided by gas-oxygen-ether from a machine. One of the chief advantages of the method is the very thing for which Dr. Mills so rightly pleads—a copious supply of oxygen. This can be achieved more surely from the oxygen cylinder than from the air drawn through an ether-soaked mask. Needless to say, proper premedication and perfectly unobstructed breathing are essential. The latter is often secured by an airway, but if necessary an endotracheal tube is used. Through these measures perfect relaxation in patients free from cyanosis and abundantly supplied with oxygen is provided daily by scores of anaesthetists. Moreover, the condition of patients after a long operation, if they have been handled in this way, is much better than that of patients who have been deeply under pure ether throughout. The machine enables us to take advantage of those periods, often considerable, when the deepest anaesthesia is not needed; at those times the patient gets gas and oxygen only. Like Dr. Mills I regard giving anaesthetics as an art, and believe that no one method should be laid down as the sole routine. Therefore I am far from disparaging open ether, and hold indeed that no student should be allowed to qualify without competence in its use.—I am, etc.,

West Middlesex County Hospital. J. BLOMFIELD.

Operations and Workmen's Compensation

SIR,—I feel that Dr. Hermann Levy's letter (July 18, p. 82) and Dr. W. O. Moore Ede's subsequent one (Aug. 1, p. 142) call for some comment.

Dr. Levy's letter in particular raises points and asks questions which, though most of the latter are rhetorical, show a misunderstanding of the Workmen's Compensation Act and, if I may say so, a biased outlook. To deal with his letter in detail.

1. What does Dr. Levy mean by "getting him back *at any price* to some sort of light work"? Surely it is in the interests of both employer and workman that the injured man should find suitable occupation as soon as possible. His financial position is thereby improved and his mind is occupied, minimizing the dangers of worry and introspection.

2. No responsible examiner acting for employers would ever suggest any operation "for . . . evil."

3. It has been my experience during many years of examining accident cases that occasions for difference of opinion with general practitioners are very rare. In any event to call a genuine difference of opinion a dispute and an employer's medical examiner an opponent betrays an attitude of mind that, if held by a workman's doctor, would go a long way to explain the patient's "very unfavourable attitude" to workmen's compensation law.

In answer to questions raised by Dr. Levy. Whether the effect of an operation is of lasting value does not bear on the question of compensation, because under the Act, if by reason of the effects of the accident or treatment for it the man's working capacity deteriorates at any time, he is entitled to receive again the appropriate weekly compensations. The question of the finding of appropriate light work is dealt with in the Act, which provides that if the workman can show that in spite of reasonable efforts he has been unable to find such work he shall be deemed to be totally uncapacitated.

The question of a subsequent accident is dealt with under the Act either as a claim *de novo*, or, if it arises as a result of disability due to a previous accident, the increased disability is regarded as the result of the first accident, and the employers responsible for the first accident are liable to pay compensation for the second. With regard to the provision of appliances, it is an almost invariable practice for the insurance company to supply these in the first instance, and in very many cases the estimated cost of replacements is covered by a "lump sum" settlement. It is, however, a weakness of the Act that no definite provision is made for this.

Dr. Moore Ede's suggestion that all cases should be referred to a neutral body—e g., the Ministry of Pensions—has been tried in Canada with, I believe, some success, but the provision in the Workmen's Compensation Act whereby an independent referee appointed for each county court may be appealed to by either side is so seldom made use of that it is very doubtful if it would be acceptable in England. This matter, however, involves many side issues—legal and otherwise—and cannot be properly dealt with in a letter. The Workmen's Compensation Act has several weak points and I hold no special brief for it, but misconception of its provisions do not assist its amendment.

—I am, etc.,

London, W 1. HAROLD GARDINER.

The Planning Commission's Report

SIR,—I have just read Dr. N. M. Vallely's letter (Aug. 8, p. 168). The point that he and many others seem to miss is just this. State medical service has to come: it is being forced on us by circumstance whether we like it or not. It is a natural result of this war, which is creating scarcities in men and material. The conditions now beginning are, if anything, likely to progress rather than to go back to where we were, and the peace is not likely to restore those conditions to what we considered as normal. Since this is so, why not envisage an *ideal* plan of State medicine, rather than try to compromise between State medicine and our present system, if such it can be called. You may never quite attain an ideal, but at least it is there to work for; but what is the result if you never quite attain a miserable compromise—and, in the end, be very sure that in a compromise the only losers will be the medical profession. We should have a well-laid plan, and we should see that the men who are responsible for its administration are not only administrators but qualified doctors as well.

The men who object to a complete State medical service, which is, as I think, inevitable, do not see that one may compromise with the present Government, but what of the Government after the war? Unless you plan ideally is it not likely that a Labour Government may whittle away that compromise until we are controlled completely? We should begin at once to build a powerful organization based on a solid plan rather than merely modify our present "system," so that when the time comes we shall rule and not be ruled.—I am, etc.,

Ledbury. GEOFFREY G. AIREY.

Self-medication and the Chemist's Shop

SIR,—Dr. E. L. Loewenthal's interesting letter raises points of great importance, but he seems hardly to realize that they have, though with no really appreciable result, been very frequently discussed in public. He should read for this purpose the evidence of the Select Committee on Stamp Duties, 1937, the P E P *Report on the British Health Services*, the debates in the House of Commons last year when the new Pharmacy and Medicines Bill was discussed, and an article on the "Druggist's Dilemma" in the *Economist* of July 12, 1941. Self-medication, if exaggerated, is certainly a deplorable thing. That the English have a certain proneness to it should be taken into account. "I hate doctors but I love medicines," says a titled lady in one of Oscar Wilde's stories. Business men have not been idle in exploiting these leanings, and it is to the credit of the B.M.A. that as long as 30 years ago it called attention to the abuses in its unforgotten publications on *Secret Remedies.*

Nobody will deny, however, that a moderate sort of self-medication is not to be condemned altogether. But that advertisements urging people to take certain patent medicines as all-in cures, that overworked and ill-paid panel doctors with little time for the single case, that overcrowded hospitals and an entirely insufficient N.H.I. scheme drive people of the poorer classes to try their own cures or the druggists' remedies, is, indeed, a tragedy. It is from all these angles that a campaign against self-medication might be started. But once undesirable causes and incentives to unjustified self-medication are removed, it is very doubtful whether further restrictions (Dr. Loewenthal ignores the existing ones) on the sale of so-called drugs and medicines in other than chemists' shops should be imposed by statute. It should not be forgotten that druggists and pharmacists not only form a profession but are also retail traders. In the latter capacity they resent that retail distributors not belonging to their "profession" sell aspirin or stomach powders or peroxide, while they themselves find no harm in selling hot-water bottles, films, toilet soap, or lavender water. If Dr. Loewenthal's restrictive recommendations were carried out the quasi-monopoly position of the pharmacist as opposed to "other vendors" would be greatly strengthened. No social advantage would result from such development. But improved health services, a more energetic control of patent medicines and their advertisements, and a careful observation by doctors of the recommendations laid down in the *National Formulary* as regards the use of non-proprietary preparations would probably help much in avoiding some of the dangers which Dr. Loewenthal has in mind, and would simultaneously cheapen the cost of treatment.—I am, etc.,

Richmond. HERMANN LEVY.

SIR,—I read Dr. E. L. Loewenthal's admirably expressed letter on self-medication and the chemist's shop (Aug. 15, p. 199) with considerable interest. While agreeing entirely with what he says, I do not think that he has mentioned the most pressing aspect of the matter. The enormous waste of material and labour which results from self-medication is not permissible at the present critical stage of the war. It is essential that we should build up a reserve of drugs for home needs, for the Forces, for the second front, and for the allies—notably China, whose gallant 8th Route Army was stated recently to have received no medical supplies from abroad for many months. To this end it is imperative that the resources of our chemical industry should be fully mobilized for essential purposes only.

In hospitals we are exhorted to use the utmost economy in the use of such things as aspirin and disinfectants, yet the well-meaning housewife may go to the pharmacist's and buy as much dettol as she likes to tip down the w.c. and the aspirin addict may purchase as much aspirin as he pleases. Surely a control over all important drugs such as that recently introduced for quinine is long overdue. They should be obtainable only for hospitals, clinics, or on a medical prescription. Strict control should also be exercised over the allotment of drugs, so that sufficient quantities are available for essential purposes over-seas as well as at home. The production of the many useless and harmful preparations now on the market should be prohibited and the labour and material diverted to necessities. —I am, etc.,

St Mary Cray, Kent BRIAN H. KIRMAN.

The Evils of Long Working Hours

SIR,—Your leading article on the evils of long working hours (Aug. 1, p. 132) is a valuable indication of the necessity for a drastic overhaul of our working conditions. May I call your attention to the conditions of another section of the community—the young laboratory assistants of both sexes? They are now chiefly recruited from secondary schools, and matriculation is the standard of general education required.

These young people of 17 or 18 years of age enter their first job enthusiastically in laboratories attached to factories, where they are employed in routine process control from 8 or 8 30 a.m. to 5.30 or 6 p.m. (with 1 hour for lunch and 15 minutes for tea if they are lucky). They have a fortnight's holiday per annum. They are encouraged by their employers to study for university degrees at evening schools, and, being intelligent and keen, they embark on courses of study which absorb an average of 4 evenings a week from 6 p.m. till 8.30 or 9 p.m. Their homework they do at week-ends or on the evenings not occupied with actual classes, but since they rarely have time for even a hurried meal between work and evening school, I have never been able to discover when they get the necessary fresh air and exercise for proper physical development.

My experience is with training these young chemists during their working hours, though I have also taught evening classes for some years. I have seen so much good human material ruined by these gruelling conditions. After a few months of this life mental and physical fatigue is apparent in all their actions. In peacetime this is bad enough, but I have seen these young people in an ordnance factory made to work daily from 8.30 a.m. till 5.30 p.m. and on alternate Saturday afternoons till 5 p.m. (instead of the usual 1 p.m.). At rush periods they have worked on Sundays too, without a compensatory day's holiday later in the week. When one has seen these youngsters of the 18 to 23 age group working for 12 consecutive days without a break in the unhealthy atmosphere of a chemical laboratory one appreciates the meaning of industrial fatigue, especially if they are handling high explosives. I know of cases where young women laboratory assistants at various stages of education between matriculation and B.Sc. work consistently for an 8-day rota of these long hours. It makes one wonder whether it is really civilization for which we are fighting, since the old pagan human sacrifice meant only death, whereas this is a refinement of slow murder.

As you so rightly point out, the young men can stand adverse conditions much better without permanent harm and in any case with a man one is dealing with an individual. But these young women, and their counterparts in factory operatives, are the mothers of the future, and it is little short of racial suicide to expose them to such unnatural strains during the difficult years of adjustment between puberty and full womanhood. We have yet to learn the extent of the damage which may be done to them. Surely an enlightened State would legislate so that continuation classes could be counted as part of the day's work and not in addition to it. If certain individuals, whether boys or girls, leave school at 17 and are considered suitable for further training they have a human right to assistance without mortgaging their future health and happiness. Surely this is in the best interests of the State as well as the individual.—I am, etc.,

London, W.4 ENID A. M. BRADFORD.

Ministerial Propaganda

SIR,—I am much interested in the furtherance of immunization against diphtheria and am doing my own little best to that end. While fully agreeing with the necessity for a campaign by the Ministries of Health and Information, I feel that their widely displayed posters might be improved upon by one or two simple alterations to the wording. In this public health department the posters have been altered so that parents are requested to "Ask your own doctor, or inquire at the council offices or at the nearest child welfare or school clinic." I think it regrettable that the private practitioner is not considered in any of the posters I have seen. Nor can I find the family doctor mentioned in the large brochure sent out by the Ministry of Health in conjunction with the Ministry of Information. At the foot of page 7 of this brochure I read: "It is suggested that local authorities should invite the co-operation of all appropriate persons and organizations in propagating the need for immunization." I wonder if the private practitioner is wrapped up in this camouflage, or is he deliberately and entirely left out of the campaign?

The word "free" looms largely on the posters and in printed speeches; I think the word "now" a happier choice. The emphasis which is laid on *free* immunization not only cuts out the private practitioner entirely but tends to suggest that were immunization not available free of cost then it would hardly be worth bothering about at all.

Local authorities are urged by the Ministry of Health to do everything possible to promote the success of the campaign. To me it seems passing strange that private practitioners are not called upon by the Ministry to take part. The family doctors' co-operation is a source of pleasure and valuable help to the average public health medical officer.—I am, etc.,

DEPUTY MEDICAL OFFICER OF HEALTH.

Persistent Blood-giving

SIR,—While it is generally recognized that the amount of blood normally lost by a donor at a sitting is such that its loss does not cause any ill effects, a point of interest appears to be raised by cases, such as occur frequently, where the same donor regularly gives blood for prolonged periods. Is it possible that although, so long as blood-giving at regulated intervals continues, no ill effects are observed the blood-forming mechanism of the body has been unduly stimulated? This might have the effect that while transfusions continued all would be well, but a cessation of blood-giving might give rise to symptoms which could only be relieved by periodical blood-letting. It would be of interest to know whether those in close contact with regular blood donors have noticed any facts lending support to such a view.—I am, etc.,

Chester. E. M. BISKE.

Obituary

SIR JOHN MACPHERSON, C.B., M.D., F.R.C.P.Ed.

Sir John Macpherson died on August 14 at Bristol in his eighty-fifth year. A son of the manse, he was born at Dores, Inverness-shire. He graduated M.B., C.M. at Edinburgh University in 1882, and immediately thereafter was appointed an assistant physician on the staff of Sir Thomas Clouston at the Royal Edinburgh Asylum. His promotion was rapid, because only seven years after graduation he was appointed to the important post of medical superintendent, Stirling District Asylum, Larbert. At Larbert he showed that he was possessed of that rare combination, deep and sympathetic clinical insight and administrative capacity. He modernized the Larbert institution, equipped a pathological department, encouraged research, and at the same time found opportunity to become lecturer in mental diseases at the Royal Colleges School of Medicine, Edinburgh, working in collaboration with the late Sir John Batty Tuke. His textbook, *Mental Affections*, published in 1899, can still be read with much profit; it contains a wealth of clinical material and experience, formulated in a clear, concise, but by no means dry manner. In association with the distinguished Edinburgh surgeon, Sir David Wallace, his brother-in-law, he became interested in the treatment of general paralysis by means of drainage of the cerebrospinal fluid. In 1899 he was appointed Commissioner in Lunacy for Scotland, and held that post with distinction until 1921. His official visits were a delight to the medical superintendents and the assistant physicians in the mental hospitals. He had always interesting and instructive suggestions to make, and gave many of us that extra word of encouragement which meant so much to us. His courtesy and kindliness were a byword amongst us all. In addition to his official duties he was of great assistance to the Scottish Office in 1913 in framing the Mental Deficiency and Lunacy (Scotland) Amendment Act; he served as president of the Special Medical Board (Military) for Scotland in 1917-18; he was a member of the Highlands and Islands Medical Board. As recognition for the great work he had accomplished the Companionship of the Bath was conferred on him in 1917, and in 1922, after he had retired from his post as Commissioner, he was knighted.

Any man might have thought that this was a fitting time to enjoy a well-earned leisure, but Sir John, still interested as he was in psychiatric work, and despite his 65 years, proceeded to Australia, delivered a highly successful series of lectures at the University of Sydney, with the result that a chair of psychiatry was founded, of which Sir John became the first professor. On his retirement, five years later, he returned to this country. A magnificent and very gallant end to a grand career.

Among other special distinctions it should be mentioned that Edinburgh University awarded him a gold medal for his M.D. thesis; in 1904-5 he delivered the Morison Lectures of the Royal College of Physicians; in 1928 he delivered the Maudsley Lecture, taking as his subject "The Present Position of Psychiatry." Finally it remains to mention that in 1910 the Royal Medico-Psychological Association of Great Britain and Ireland conferred on him its highest honour, the presidency.

Now has ended the distinguished career of one of Britain's foremost psychiatrists—a man who up to the very last interested himself in his specialty, and always had a kindly greeting and a helping hand for those of us who were so much junior to him, and owed him so much. Clear-headed, wise, courteous, he had wide cultural and scientific interests which he applied constructively in building up a better psychiatry.

As stated previously, he married a sister of Sir David Wallace, the well-known and distinguished Edinburgh surgeon, and is survived by her and their two daughters, the elder of whom is a B.Sc. of Edinburgh University, while the younger is at present serving with the military Forces as a nurse in the V.A.D.

D. K. H.

JOHN M. T. FINNEY, M.D.

Dr. John M. T. Finney, who died at his home in Baltimore on May 30 at the age of 78, was well known to surgeons in this country as one of the most distinguished members of the staff of the Johns Hopkins Hospital. He belonged to that rapidly diminishing band who were closely associated with Prof. Halsted as assistants in the early pioneering days at Johns Hopkins, for he joined the medical faculty there as long ago as 1893 and ultimately became professor of surgery. John Finney occupied all the important positions in surgery in the United States, including the presidency of the American College of Surgeons, the American Surgical Association, and the exclusive Society of Clinical Surgery, as well as many other bodies. In 1936 he was awarded the Henry Jacob Bigelow Medal for his distinction in and contributions to surgery. During the last war Finney accompanied the American Expeditionary Force to France and acted as chief surgical consultant with the rank of Brigadier-General. For these services he received the D.S.M., but what he much more valued was the gratitude of those large numbers of medical officers who came under his purview and received willing guidance at his hands. In this country he was well known and respected and received many distinctions. Since 1920 he had been an Honorary Fellow of the Royal College of Surgeons of England. He was also an Honorary Fellow of the Medical Society of London and of the Irish College of Surgeons. Finney was in the truest sense a general surgeon, with perhaps a particular interest in the abdomen. As long ago as 1902 he introduced the method of pyloroplasty which has always been associated with his name, but there were many other contributions to practice which have not become eponymous. He made several visits to this country and took part in meetings of the British Medical Association and the Hunterian Society. At home he was generally recognized as a sound surgeon and good teacher, but most of all as a great doctor and an influence for all that was good in the profession. Among his pupils and associates he will always be remembered for the way he put the interests of his patients before all else. Finney had a keen sense of humour, which sometimes took a whimsical turn. He was a great gentleman, and though his loss will be severely felt, there is no doubt that his example and memory will for long continue as an influence in the healing art as practised in America.

G. GREY TURNER.

L. F. WILSON, M.B.

The East Yorkshire Branch of the B.M.A. has lost one of its staunchest supporters in the death on August 7 of Dr. LESLIE FREDERICK WILSON at the comparatively early age of 54. Dr. Wilson served during the last war with the R.A.M.C. and then, in 1924, qualified M.B., Ch.B. at the University of Birmingham. For several years he practised in the Dudley area, and his medico-political activities during that time included being hon. secretary of the Dudley Division (1926-30) and representative at the Annual Meeting at Manchester in 1929. In 1930 he went to East Hull, where he soon established a large practice. There he associated himself with the work of the St. John Ambulance Brigade, being appointed Divisional Surgeon to the Alexandra Dock (L.N.E.R.) Division; in 1938 he was promoted to Corps Surgeon, Hull Corps, St. John Ambulance Brigade, and in the following year to County Surgeon for East Yorkshire. He lectured a good deal on first aid and conducted many examinations for the Brigade's certificate. As a judge in local first-aid competitions he showed a keenness and understanding which resulted in his being asked to judge the Brigade finals in London on one occasion. Dr. Wilson trained a competent staff which has served at the East Hull First-Aid Post under dangerous and difficult conditions. On one occasion ambulances could not reach the post to take the injured to hospital, so Dr. Wilson and his staff improvised a temporary hospital at the post. They worked with the aid of hurricane lamps and candles, and heated the premises with stoves. The post was damaged during other "incidents," but it always carried on under Wilson's untiring and inspiring leadership. For his services he received the M.B.E. (Civil Division) last November. He had many medical interests, and at the time of his death was a member of the East Yorkshire Branch Council, the Local Medical War Committee, the Hull Local Medical and Panel Committee, the Study Group of the Branch and convener of the subgroup for East Hull, and vice-chairman of the Hull Public Medical Service. He was also an active member of the Hull Medical Society.

Dr. Wilson's opinion was highly valued, always concisely expressed, and punctuated with good humour. He had a great sense of duty, and on many occasions visited his patients when he should have stayed at home. Although obviously seriously ill on July 26 he felt it his duty to attend a meeting of the Local Medical War Committee. He was always ready to help his colleagues however busy he might be, and never lost his pleasant and cheerful bearing. The affection and high esteem with which he was regarded were demonstrated at his funeral, which was attended by representatives of all the various organizations with which he was connected.

C. J. P. writes: Leslie F. Wilson was one of 4 medical students who were closely associated throughout 5 happy, if arduous, years. He set out on a medical career under a heavy handicap which would have deterred all but a resolute soul such as his. Several years older than the majority of students and fresh to study after 4 years on active military service were not the only difficulties he faced and overcame. L. F. had no pretensions, and if he won no prizes his knowledge was sound and of practical value. Despite his handicap he took each examination fence as it came and graduated in due course without a single fault. He was a staunch friend and ever a cheering companion. A rough diamond, may be, but he had the diamond quality. He was the right man to have at hand in a tight corner, for he was never afraid of heavy odds. It is no wonder, therefore, that his work in Civil Defence gained him the M.B.E. He would be at his best, and be one of the best, in charge of a busy first-aid post. His patients were fortunate in their doctor. There will be many who know of his untiring zeal and complete unselfishness, without thought of gain, on their behalf. His 3 fellow students will remember his energetic example and stimulating companionship with gratitude.

We regret to announce the death on August 4 of Dr. **STEVEN LONGMORE BUTTERWORTH WILKS**, a familiar figure in the life of Colwyn Bay, where he had practised for 33 years. Dr. Wilks received his medical education at the University of Leeds, qualifying M.R.C.S., L.R.C.P. in 1892. In the same year he took the M.B., B.S. of London, proceeding to the M.D. in 1900. He also took the M.B., Ch.B. of Leeds in 1905. Wilks first began practice at Grassington, Wharfedale, where he often used to visit his patients on horseback. From there he went to Colwyn Bay, where, in addition to a busy practice, he was attached, in one capacity or another, for all his professional life to the Colwyn Bay and West Denbighshire Hospital. For over 30 years he was physician and anaesthetist, for some years senior physician, and later honorary consulting physician and honorary consulting anaesthetist to the institution. His hospital work was, perhaps, dearer to him than any other part of his professional life. He took an active interest in all that went on there, and for years the Board of Management benefited by his far-sighted views and sound advice. Dr. Wilks was most sought after as an anaesthetist; he had given thousands of anaesthetics at the hospital, and his surgical colleagues had come to place reliance on his judgment. For many years he was an active member of the B.M.A. and in 1935–6 was chairman of the North Caernarvon and Anglesey Division. A colleague writes: "Dr. Wilks had a sunny, cheerful nature and it was a privilege to be his friend. He was of a modest and retiring disposition, and men are rare who are moved so little by a mercenary motive. He was not ambitious in the ordinary sense of the term, but his ambition was to do good work all day in the service of his fellow men, and as a result he was an exceptionally happy man."

The Services

The Military Cross has been awarded to Capts. R. E. S. Lewis and C. D. Weir, R.A.M.C., and to Capt. A. G. J. P. Fernandes, Capt. R. D. Scriven, and Lieut. D. J. Burnett, I.M.S., in recognition of gallant and distinguished services in the Middle East.

The R.N.V.R. Officers' Decoration has been awarded to Surg. Cmdrs. W. H. Butcher, J. B. Oldham, and H. M. Petty, R.N.V.R.

CASUALTIES IN THE MEDICAL SERVICES

An Admiralty Casualty List published on July 28 gave a list of the ship's complement lost in H.M.S. *Hermes*, aircraft carrier, sunk by enemy action in the Bay of Bengal in April. Among them was Surg. Cmdr. **JAMES MICHAEL MCNAMARA**, R.N. He was educated at the National University of Ireland, in Dublin, where he graduated M.B., B.Ch., B.A.O. in 1923. After a period in practice he entered the Royal Navy as surg. lieut. in 1929, became surg. lieut.-cmdr. in 1934, and surg. cmdr. in 1940.

Lieut.-Col. **HOMI RUSTOMJI CURSETJI**, I.M.S., is included as "Died" in an India Office Casualty List published on August 14. He was born on August 13, 1890, and graduated M.B., B.S. of the University of Bombay in 1916 and also took the D.O.M.S. of the English Royal Colleges in 1937. He entered the I.M.S. as temp. lieut. in 1917 and in 1922 received a permanent commission, being ranked as capt. from 1920. He was promoted capt. in 1923, major in 1928, and lieut.-col. in 1936. He served in the war of 1914-18.

Prisoners of War.—Capt. E. F. M. Caraher, R.A.M.C., Capt. A. F. Murray, R.A.M.C., Major J. M. Officer, R.A.M.C., Lieut. A. C. Price, R.A.M.C., Major L. F. Richmond, R.A.M.C., War Subs. Capt. R. L. Sanderson, R.A.M.C., War Subs. Capt. D. B. Watson, R.A.M.C.

Wounded.—Acting Col. D. V. O'Malley, O.B.E., I.M.S.

DEATHS IN THE SERVICES

Colonel **WILLIAM RIACH**, C.M.G., late R.A.M.C., died at Chula Vista, California, on May 29, aged 70. He was born in Edinburgh on May 24, 1872, and graduated as M.B., C.M. in 1894 at Edinburgh University; he proceeded M.D. with commendation in 1899, also taking the D.P.H. of the Scottish Colleges in 1898. After filling the posts of resident physician at the Edinburgh Royal Infirmary and clinical assistant at the Royal Westminster Ophthalmic Hospital, he went to South Africa as a civil surgeon to serve in the war of 1899-1902. After about eight months' service in that capacity he took a permanent commission as lieutenant in the R.A.M.C. on Nov. 29, 1899, reaching the rank of lieut.-colonel in Feb., 1918. In the South African War he took part in operations in the Orange River Colony and in Cape Colony, receiving the Queen's medal with two clasps. He also served throughout the war of 1914-18, being mentioned in dispatches in Jan., 1916, and receiving the C.M.G. and a brevet colonelcy.

Medical News

The annual general meeting of the British Orthopaedic Association will be held at Nottingham on Sept. 25 and 26 under the presidency of Mr. G. R. Girdlestone. On the morning of Sept. 25 a clinical meeting will be held at the Harlow Wood Orthopaedic Hospital; in the afternoon a discussion on rehabilitation, followed by a demonstration, will be held at the Rehabilitation Centre for Miners, Berry Hill, near Mansfield. On Sept. 26 the meeting will be continued at the General Hospital, Nottingham.

The Home Office announces that Major John Gilmour, C.M.G., *M.C.*, Department of Health for Scotland, has been appointed to fill the vacancy for a temporary Inspector under the Cruelty to Animals Act, 1876.

The committee of award of the Norman Gamble Fund and Research Prize will consider applications for the prize and for grants in aid of research work in Oct. Applications for the prize and for grants in aid must be received by the Secretary of the Royal Society of Medicine, 1, Wimpole Street, London, W.1, not later than Sept. 30.

Dr. P. Gorer of Guy's Hospital will give a lecture entitled "Experimental and Genetical Study of Leukaemia and its Relations to Cancer Research" to the Association of Austrian Doctors in Great Britain on Sunday, Sept. 6, at 11.30 a.m., at 69, Eton Avenue, N.W.3.

Since the beginning of the war over 300 field medical units have been raised in India and are being used in the United Kingdom, the Middle East, and other areas where there are British and Indian troops, while ambulance trains, fully equipped and manned by personnel from India, have been provided for the Eastern theatres of war. These field units did not exist in peacetime, but had to be raised and staffed on the outbreak of war. Although there has been a rapid increase in the number of medical personnel there are not enough to meet future commitments, and many new training schools have, therefore, been started and the existing ones expanded. Consultants from the United Kingdom are helping India in this work. A new, centrally controlled Army medical store organization has been created in India, which is not, however, confining its services to the Army, but is also supplying the Royal Indian Navy and the Royal Air Force. It has, on occasion, provided medical assistance for the American, Chinese, and Russian Armies.

A hospital for the wives of officers and men in the Forces has been opened at Adlington Hall, Cheshire. There is a resident medical officer with special experience in obstetrics, and the consultant obstetricians of Saint Mary's Hospitals, Manchester, pay regular visits and attend whenever required. The fee of £5 5s. a week, which, in a few special instances, may be reduced, is inclusive of medical attention (including visits by the honorary staff), drugs, dressings, etc.

Proposals for the inauguration of a Regional Hospitals Council for Northern Ireland were discussed at a conference in Belfast recently, which was attended by representatives of the Nuffield Provincial Hospitals Trust and of local municipal and voluntary hospitals. The first steps towards this were taken a year ago, when a delegation of the Trust was received by the Governor of Northern Ireland at a conference called to consider a hospital co-ordination scheme for the Province.

Mothers of premature infants can obtain, on presentation of a doctor's certificate, a permit authorizing them to spend additional "points" on condensed milk when supplies are available. The certificate, which should be on a form to be obtained from local food offices, should state that the infant is a premature one, is under the age of 6 months, and needs condensed milk, the weekly quantity needed being also stated. All infants under 1 year are to have a priority supply of liquid milk up to 2 pints daily. It may be taken either in the form of liquid milk or as half liquid and half national dried milk.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the notifications of measles fell by 857, of whooping-cough by 163, of scarlet fever by 116, and of diphtheria by 70.

The infectious diseases of childhood are prevalent in only a few counties. Scarlet fever and diphtheria are relatively more common in the Northern section of the country than in the Southern. Measles and whooping-cough do not show this geographical difference. This can be illustrated by expressing the notifications in the chief centres of the two sections of the country as a percentage of the total. The percentage distribution for the week under review was:

	Whooping-cough	Measles	Scarlet Fever	Diphtheria
Lancashire and Yorks West Riding	25	32	28	29
London, Middlesex, and Essex	19	26	14	8
England and Wales	100	100	100	100

The notifications of dysentery were 18 higher than in the preceding week. Two small outbreaks occurred in Berkshire, Wallingford R.D. 6 cases, and Hertfordshire, Hemel Hempstead M.B. 9 cases.

In *Scotland* 85 cases of dysentery were notified, compared with 52 in the preceding week. The chief of the local outbreaks were those of Fife County 37 cases, Aberdeen City 22, and Edinburgh 8.

Infectious Diseases in Port Areas

The experience of Glasgow has led to additional precautions being taken by Bristol Port Health Department. Every ship and the crews entering port are to be examined to reduce the risk of importing infection.

Typhoid and Paratyphoid Fevers

A report has appeared in the daily press attributing to Mr. Ernest Brown, Minister of Health, the statement that not one case of typhoid or paratyphoid occurred in this country during 1941. The publication of such a statement is rather surprising in view of the epidemic of last summer in the Liverpool area, which, originating in a multiple baker's business, involved some 800 persons. Altogether there were 4,703 notifications of paratyphoid and typhoid fevers in England and Wales during 1941, with 148 deaths—a fatality rate of 3.1%. The trend of these diseases during the present year has been exceptionally low, the number of notifications during the first 30 weeks of the last six years, 1937-42, being 1,004, 672, 659, 1,340, 3,227, and 502.

Memorandum on Scabies

The Ministry of Health has issued a revised edition of the Memorandum on Scabies which was published in January, 1940: it deals with the condition under the headings of "Life History and Habits," "Symptoms," "Complications," "Differential Diagnosis," "Method of Spread and Prevention," and "Treatment." It can be obtained at H.M. Stationery Office for 1d.

Returns for the Week Ending August 15

The notifications of infectious diseases in England and Wales during the week included the following: scarlet fever 1,332, whooping-cough 1,125, diphtheria 665, measles 4,983, acute pneumonia 440, cerebrospinal fever 70, acute poliomyelitis 15, dysentery 51, paratyphoid 13, typhoid 15.

No. 31

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 8.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942 (a)	1942 (b)	1942 (c)	1942 (d)	1942 (e)	1941 (Corresponding Week) (a)	1941 (b)	1941 (c)	1941 (d)	1941 (e)

---

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Treatment of Seborrhoea

F.R.C.S. would be most grateful to any reader who could help him to be relieved of a chronic troublesome skin complaint described as seborrhoea. It occurs in small brown patches on his bald head and temples and spreads at the periphery. The patches can be peeled off sometimes in thin small flakes, leaving a sore place with crusts. It does not yield to ointment of sulphur with benzoic and salicylic acids—the usual treatment advised.

Itching of Limbs

Dr. **William Stobie** (Oxford) writes: Has Dr. W. A. Milligan (Aug. 15, p. 208) tried cannabis indica, first brought to my notice by the late Dr. Wm. Collier?

Coltsfoot

Dr. **C. W. Badger** (Penicuik) writes: I asked an old patient who has used coltsfoot for some time to give me a note on it. I enclose his note. Its use seems to keep him quiet.

"In regard to query about coltsfoot I have collected and smoked this for some considerable time. So far as I am aware there is no hard-and-fast rule as to the time for collecting the leaves, although August is said to be the best time. However, I have collected them in all stages of their development, from their first appearance to the withering stage, and found no practical difference. The leaves are simply collected and dried in the sun, or at the fire, until absolutely dry or nearly so, then rubbed down to shreds and packed in an air-tight tin. Sometimes they are mixed with a little lavender to give the smoke a perfume. Since 1921 I have been subject to occasional attacks of asthma, at times severe, but since starting to smoke coltsfoot and inhale the smoke I have had only one slight attack which I think was brought on by a chill."

Premaxillary Cysts

Mr. **H. T. Roper-Hall** (Birmingham) writes: Will members of the profession please let me have details, models, radiographs, specimens, or histories of cysts in the premaxillary region; especially those in the region of the lateral tooth, in which diagnosis was complicated or origin uncertain and the teeth not, apparently, involved. Material will be appreciated and acknowledged; all specimens, etc., will be returned.

Income Tax

Billeting Allowance

"Q" is a pathologist in the E.M.S., receiving a salary of £800 and an extra allowance of £100 as he is "billeted." He is keeping his home going and visits it each week-end. Is he liable to income tax on the £100?

⁂ As it is money paid and received under a service contract and as the expenses with regard to which it is paid are personal in general character the amount in question appears to be legally liable to assessment.

LETTERS, NOTES, ETC.

Loss of Hair after Air Raids

Mr. **Frank Bodman** (Bristol) writes: The case of depression–hyposexual–alopecia syndrome (July 18, p. 67) reminds me of a man, aged 36, whom I saw last year, who lost all his hair following experiences in air raids in Bristol. He was a fireman attached to a railway goods yard, and had a series of alarming incidents to deal with. He lost all his scalp hair and his eyebrows, but retained his beard and axillary and pubic hair. Emotionally he was stable. There was no evidence of depression, and he experienced no loss of sexual feeling or power. He was merely self-conscious about his peculiar appearance. Under a course of ultraviolet-light treatment he recovered his hair and eyebrows, although at first the hair returned in patches, so that during the recovery stage he resembled a case of alopecia areata. There was no greying of the new hair.

Bed-pan for Patients with Fractured Femur

Dr. **W. J. Gunne** (Kenora, Ontario) writes with reference to "Naval Patient's" comments on the hospital bed-pan (June 6, p. 710): In the old days when we used Liston's long splint in fractures of the femur (and good results we got, too) we made a mattress as follows. Out of the centre of a mattress on one side we removed a portion of the mattress and slid in the bed-pan. After use it was removed and replaced by the portion of the mattress. We found this worked well.

Declining Population

Dr. **B. Dunlop** writes: I welcome the statements of Mr. V. B Green-Armytage that no one finds fault with spaced births after the first child and that it is impossible to suppress birth control. But I know many medical colleagues who will share my disagreement with the view that freedom for birth control spells race suicide and economic ruin, and I regret that it was expressed in a journal which cannot give space to economics.

Mrs. **Marie C. Stopes**, D.Sc., writes: The letter from Mr. V. B. Green-Armytage in your issue of Aug. 1 raises several points which on the face of it appear rather conflicting. It is very important, however, to know what method of control of conception he approves, since he says: "No one finds fault with spaced births after the first child." I sympathize greatly with his condemnation of "quinine and mercury and other noxious ingredients." Compounds of mercury are now, alas! being encouraged by the society of which Lord Horder is the president in spite of my unavailing protests. Perhaps your readers may find it useful to know that headquarters constructive birth control clinics are available for free patients in the following towns and these are all open daily from 10 to 6: Aberdeen, Belfast, Cardiff, Leeds, and London. At these clinics no noxious substances of any sort, but only absolutely bland and safe contraceptives, are supplied.

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* for August 27, 1842:

"In our last number we mentioned the changes which had recently taken place in the medical department of the University of Edinburgh. Dr. Home has resigned the chair of practice of medicine, to which Dr. Alison has been unanimously elected, and Dr Henderson fills the chair of pathology, vacant by the resignation of Dr. Thompson. The election of Dr. Alison to the chair of practice of physic cannot fail to be most beneficial to the university. The truth is, that time had laid his heavy hand on many of the professors, and the state of oral instruction had become intolerable. Dr. Home especially was long since physically incapable of fulfilling the duties of the office which he held. It is now many years since we assisted at a lecture given by the worthy professor. The pupils were '*rari nantes*' in the vast amphitheatre; one half of them were playing cards; the other half listening to the notes of an old violin, on which an Irish student was playing 'Home, sweet home'; while the professor, unconscious of that which was passing on above him, mumbled from an ancient manuscript words unheard by himself, and unheeded by his pupils. The valedictory letter of Professor Home to the University of Edinburgh is worthy of being placed on record; it is thus conceived:

'Edinburgh, August 8, 1842

My Lord,—Having for forty-four years discharged the duties of the chairs of materia medica and of the practice of medicine; considering also that, from my very advanced age (although still enjoying the most perfect health), I am become unable to perform the important duties of the professorship, which I now hold, also wishing, before I go home, to have some time free from my laborious duties, I have for some time intended, and now herewith offer to your lordship and the other honourable patrons of the college, to resign the professorship of the practice of medicine, on condition of your providing a retiring allowance of £300 sterling per annum, and making such other arrangements as may seem necessary for securing the requisite payments of the said allowance during my life.—I am, &c.

James Home.

To the Right Hon. the Lord Provost.'

The £300 per annum with which the career of the professor thus characteristically terminates is to be taken from the pockets of his successors, £150 being paid by Dr. Alison, the remainder by the professor of theory of medicine. It is questionable how far it may be a prudent measure to leave the burthen of Dr. Home's retiring pension on his successors; but we suppose that it was a matter of necessity, and that the university possesses no funds whence the pension could be derived. But enough of Dr. Home and his pension; the subject on which we are desirous of saying a few words is the election to the chair of pathology."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY SEPTEMBER 5 1942

AN ALPHABET OF BREAST-FEEDING

BY

CHARLES McNEIL, M.D., F.R.C.P.Ed.

Paediatrician, Maternity Pavilion, Royal Infirmary, Edinburgh

In this third year of war the saving of food is an urgent duty, and the waste of food is strongly and rightly denounced. It is timely, therefore, to draw attention to the serious waste of breast milk caused by the prevalent neglect or mismanagement of breast-feeding. Breast milk is the ideal and complete food of the infant for the first six months of life and can continue to be its principal article of diet for the remainder of the first year. The gross quantity of breast milk consumed by a baby in six months is about 210 pints (on the basis of 3/4 pint daily for the first month and 1¼ pints daily for the next five months). Deducting the 41,459 infant deaths in Great Britain during 1941, there were 635,062 survivors, and their requirements in breast milk for the first six months were 16½ million gallons. It is a reasonable estimate, and probably an under-estimate, that one-third of this quantity, 5½ million gallons, of essential ideal infant food was lost through unnecessary weaning of babies.

Of babies weaned early the great majority are weaned in the first month of life. In my ward at the Edinburgh Children's Hospital 62% of a consecutive series of 100 babies had been weaned by the end of the first month, and by the end of the second month the figure was 80%. It will be agreed that this early weaning of babies is due to the failure of mothers, nurses, and doctors to overcome the numerous difficulties in breast-feeding that occur in the first weeks of lactation. For a generation the pre-eminent value of breast milk has been taught and accepted ; but this has had little effect in practice, because, on the occurrence of difficulties, weaning is advised for reasons that are far too often trivial and unnecessary. The results are not only a colossal waste of the best infant food available but also a waste of money, time, and trouble, and a loss of thousands of lives. This is bad enough in times of peace ; it is worse in time of war, when the substitute, cows' milk, is scarce and urgently needed for older children, and when the conservation of infant life and health is a paramount duty.

The following simple account of breast-feeding, its normal processes, and difficulties is offered to nurses and doctors in order to assist them in their duty of securing and maintaining breast-feeding in every possible case. It might be called the A B C of the subject—an alphabet of breast-feeding.

The Normal Processes of Breast-feeding

Breast-feeding is not so simple as it looks, and its inauguration is beset with many difficulties. But these difficulties can be understood and overcome only if the underlying facts of normal structure and function are known.

(*a*) *Breast-feeding.*—This is not a single process but a triple one, consisting of lactation, suckling, and digestion. For each there are anatomical and physiological data. In each the normal process may be at fault ; so that difficulties may arise in lactation, suckling, and digestion.

(*b*) *Lactation.*—This consists in the production of milk in the mammary glands and its temporary storage in the dilated great ducts behind the nipple. Efficient lactation depends, among other things, on the regular emptying of these ducts by suckling.

(*c*) *Breast Milk.*—For the first two or three days breast milk consists of scanty thick colostrum. About the third day there is a free flow of thin breast milk, accompanied by engorgement of the breast. At the end of the first week the daily output of milk, when mother and baby are healthy, is about 15 oz. ; at one month, 20 oz. ; at three months, 25 oz. ; and at six months, 30 oz. These daily quantities can be easily checked by test-feeding.

(*d*) *Suckling.*—This is a co-operative act of mother and baby. Its success depends upon many things : upon the practical skill of mother and baby, both of whom may require training by the nurse in the first week ; upon the healthy condition and shape of the nipple ; upon the complete emptying of the milk ducts at each suckling ; upon the complete eructation of swallowed air, a process which again requires deliberate patient training in the first days.

(*e*) *Digestion.*—Daily inspection of the tongue is important The chemical processes of early digestion are less important than the mechanical. Early vomiting is often due to maladjustment of the pyloric sphincter with the contraction of the body of the stomach, or to retained air, and is rarely due to organic pyloric obstruction. The early peristaltic action of the intestines is vigorous and produces three to four stools a day. The colour of the stools changes from dark green to bright yellow about the fourth day, but a light green stool at this stage may be physiological or the result of milk excess.

Difficulties of Breast-feeding

The complete list of difficulties is a long one. They may arise from disturbance or fault in lactation, suckling, or digestion ; from general illness in mother or baby ; from psychological faults in mother and baby. Some of these difficulties are irremediable and call for weaning ; but most can be overcome easily, or by patience and perseverance. In the list that follows the unmanageable difficulties are marked − ; the manageable are marked + ; and those that are doubtful − +. The great majority of all these difficulties occur or become obvious towards the end of the first week. In this list there is a broad grouping into maternal and baby difficulties , nearly all the unmanageable difficulties (and they are few) occur in the maternal group. A group with an asterisk (*) indicates that unnecessary weaning is common in this group.

Maternal Difficulties

General

*(*f*) *Psychological* (+).—Maternal unwillingness, fear, anxiety, and ignorance form a group in which the difficulty is in an attitude of mind. At the present time it is a large

group, and is responsible for many cases of early and unnecessary weaning. It is kept large by the connivance and consent of nurses and doctors ; and it could be greatly reduced at once by our own assurance and by reassurance and persuasion of the mother.

(*g*) *General Physical Illness* (− +).—This is a miscellaneous group that includes the serious complications of labour, chronic heart disease, pyelitis, anaemia, malnutrition, and acute illness. The deciding factor is the condition of the mother and the effect of lactation on her general health. In many cases weaning is called for ; in many, lactation can proceed without injury to the mother and with advantage to the baby. In only one case is the bar to nursing absolute ; and that is maternal tuberculosis, in which lactation and suckling are dangerous to mother and baby alike.

Lactation

(*h*) *Excessive Engorgement of the Breasts* (+).—This is a common event in the middle of the first week, and may cause great local discomfort and some general upset ; but it is transient and is easily reduced by gentle manual expression of milk, compresses, and an aperient. It is often a herald of abundant lactation. True mastitis with abscess formation generally occurs later, and calls for suspension of suckling from the affected breast for two or three weeks. When healing is complete, lactation can be re-established.

(*i*) *Nipple Conditions.*—(1) *Fissure of the Nipple* (+) is caused by lack of ante-natal care, by excessive suckling in the early days of lactation, by breast engorgement, etc. It is treated by withdrawal of suckling for from four to seven days, by manual expression of milk, and by frequent careful dressing of the lesion with soothing and/or astringent lotions. (2) *Retraction of the Nipples* (− +) is a more stubborn difficulty, and is treated by softening, mobilizing, and pulling out of the nipples, while lactation is maintained by manual expression. Treatment may fail.

*(*j*) *Scanty or Diminishing Lactation* (− +).—This can be guessed if the baby is hungry, is angry after suckling, and has small infrequent stools ; it can be easily verified by test-feeding (a daily output of 10 oz. or less at the end of the first week means inadequate lactation). It is treated by suckling of both breasts for shorter periods and at shorter intervals, by manual expression of milk after suckling, by stimulation and mobilization of the breasts, by improving maternal digestion and nutrition, and by giving the baby *small* supplementary feeds which prevent loss of weight but maintain a state of slight hunger and active suckling. These measures should be continued for two weeks, and should be controlled by occasional test-feeding. They are generally successful in the early cases ; but less often if the decline shows itself in later lactation.

(*k*) *Excessive Lactation* (+).—This is common and often enough produces digestive disturbance—gastric flatulence and vomiting, and large frequent stools. It is easily put right by reducing the number of feeds and the period of suckling.

Suckling

(*l*) *Mismanagement of Suckling* (+).—This is another important group. The inexperience and ignorance of the mother may result in clumsy handling of the newborn during suckling, allowing the baby to fall asleep at the breast, too prolonged suckling, and neglect of the important technique of breaking wind. All these faults can be easily removed by the patient expert instruction of the midwife.

Baby Difficulties

Suckling

(*m*) *Mismanagement by the Baby* (+).—The baby, like the mother, may be unwilling to play his part, or may be ignorant and inapt. And so we have the not uncommon early refusal to take the nipple ; however stubborn the battle between nurse and baby, this refusal is always overcome by withholding food (not fluid). Also, the baby who falls asleep at the breast must be kept awake and goaded into action.

Digestion

(*n*) *The Mouth.*—Observation of the mouth ought to be part of the daily routine of the nurse. Thrush and other forms of stomatitis interfere with breast-feeding, and their early detection allows rapidly effective treatment. Deformities of the mouth may or may not impede suckling.

*(*o*) *Vomiting from Gastric Catarrh* (+).—This is due to infection of the stomach by the swallowing of infected material from the vagina, causing vomiting in the first two or three days after birth. It is treated by giving water only for 12 hours, with a little sodium bicarbonate or magnesia ; and, if necessary, by washing out the stomach.

*(*p*) *Vomiting from Gastric Spasm and Flatulence* (+).—The two conditions need not be combined, but often are so. The vomiting is usually quiet, frequent, and small, but may be forcible. The baby is of the restless type, impatient in suckling and wriggling about afterwards. Treatment is entirely a nursing procedure. Suckling should be interrupted several times "to break wind" ; on its completion a further patient effort should be made to produce eructation, and the baby soothed to sleep in the upright position before being laid down in his cot. In this type of disturbance the feeding interval should not exceed three hours, and with advantage may be less. These measures must be patient and thorough. Weaning in these cases is a bad blunder, and is often followed by persistent frequent vomiting for months.

*(*q*) *Vomiting from Excess of Milk* (+).—This may produce little disturbance beyond the spilling up of milk after suckling and the passage of frequent large stools ; or it may give a similar clinical picture to that of section *p*. A few test feeds will disclose the condition. The remedy is simple and effective—to reduce the number of feeds and cut down the period of suckling to 15 or 10 minutes.

*(*r*) *Vomiting from Pyloric Obstruction* (+).—This is rare until the end of the second week. The clinical features of pyloric stenosis need not be described, nor its specific treatment. But *breast-feeding must be maintained*: its continuation will greatly favour the success of any treatment, medical or surgical. Weaning in cases of pyloric stenosis is still far too common, and the mistake is costly in lives. Indeed, the *rule is absolute for this and every other type of vomiting—never to wean on account of the baby.* The only exception is the excessively rare condition of anaphylactic vomiting ; and its rarity serves only to prove and uphold the validity of the rule.

(*s*) *Intestinal Flatulence* (+).—If this causes colic it is easily recognized. But there is a silent type in which there is no colic ; and the baby, fat and flourishing, is happy throughout the day but cries through wakeful hours at night and disturbs the peace of the household. Such babies put on weight rapidly and take large feeds quickly, which carry through a little swallowed air into the intestine. The condition may seem too trivial to require treatment, but in the long run nervous injury is done through loss of sleep. *Treatment:* Reduce intake by cutting down the period of suckling ; slow down the rate of feeding ; take special care in "breaking wind."

(*t*) *Frequent Large Greenish Stools* (+).—These are due to excess feeding, and the remedy is to reduce the number of feeds and the period of suckling. Small doses of paraffin emulsion will control any accompanying catarrh.

(*u*) *Constipation* (+).—One type of constipation fairly common in breast-fed babies in the early months is of special character and seldom described in books. There is no bowel movement for two or three days, and then the passage of a large soft healthy motion. General health and digestion are excellent. The cause is anal spasm (not fissure) ; and the remedy is to pass the little finger covered with vaseline into the anal canal and keep the sphincter dilated until the lower bowel and rectum contract and expel the stool. This is done twice daily until there is a spontaneous daily movement, and thereafter once daily for a week.

General Conditions

(*v*) *Prematurity* (+).—Breast-feeding is especially valuable in premature and feeble babies ; but lactation is likely to be delayed, particularly if the stimulus of suckling is lacking. The special methods of feeding in prematurity cannot be detailed here ; but lactation can be encouraged by manual expression of the breasts, and when small amounts are obtained these can be given to the baby. It is surprising how a small feeble baby of 4 lb. or less, and a fortnight old, will at once suck the nipple vigorously. Before breast milk is available a diluted sweetened condensed milk is the best food ; its low fat value is an advantage.

(*w*) *Gastro-enteritis* (+).—This dangerous condition is rare in breast-fed babies at home ; but it is an ever-present risk in institutions. Vomiting and diarrhoea are accompanied by the essential symptoms of sudden anorexia, grave weakness, and dehydration. Inmmediate drastic treatment consists in total withdrawal of milk for one, two, or more days, the substitution of sweetened alkaline water, the giving three or four times daily of small doses of magnesia (a half to one teaspoonful), and parenteral salines. Meantime, lactation is maintained ; but breast milk is resumed only when the colour and the strength of the baby have improved and there are signs of hunger and returning appetite. At first the breast milk, given by bottle, should be skimmed and diluted. In the acute stage a little sweetened tea twice daily is of value.

(*x*) *Failure to Gain Weight, and Poor Appetite* (+).—This condition is common at the end of the first week. Hunger and appetite can be restored quickly by the withdrawal of two or three breast-feeds and the substitution of sweetened water preceded by half-teaspoonful doses of magnesia. This can be repeated, if necessary, on a second day.

(*y*) *Febrile Illness in the First Month* (+).—This may be dehydration fever or any other sharp and transient febrile illness. The dietetic treatment is the withdrawal of breast-feeding for 12 to 24 hours and the substitution of abundant sweetened fluid ; and here, again, the diuretic and diaphoretic action of tea infusions can be used with good effect. Breast-feeding can then be resumed.

(*z*) *Etcetera* (+).—Among all other pathological states in the baby during the period of breast-feeding—whether organic, structural, functional, or infective—while some may require a temporary withdrawal or modification of breast milk, there is not one which contraindicates breast-feeding.

Conclusion

This brief epitome of breast-feeding makes a crowded presentation of a large and complicated problem of dietetics. In other branches of dietetics the doctor and the nurse are not concerned with the production of the food, nor with its conveyance to the patient, but only with doling it out. But in breast-feeding we have to supervise all three operations ; and before we can do this we must know and understand the processes that underlie lactation, suckling, and digestion. Only when we are instructed in this primary knowledge can we manage the normal dietetic problem of breast-feeding. And when we are so instructed we can then understand and deal successfully with the derangements that may upset these three physiological processes. It would not matter much if we had mastered the problem of the infant dietetics of cows' milk, complicated as it is with the far greater risk of infection. For in using cows' milk we face the double problem of malnutrition and infection, and our failure is shown in our high infant death rate.

Human milk is a food perfectly designed in its chemistry for the digestion and nutrition of the infant ; and in the arrangements for its supply and consumption it is almost proof against infection ; with these supreme advantages, it is also the cheapest of all human food, and the least troublesome to give.

But breast-feeding is not an automatic process ; and its inauguration is attended by many checks and difficulties. Most of these difficulties can be overcome by knowledge and patient effort ; and in this paper I have tried to set out in an orderly way the common difficulties and their simple remedies. The general neglect and mismanagement of breast-feeding has existed so long that its failure has become accepted as an inevitable effect of our civilized society. Actually it is one of the major problems that have to be faced in any serious effort to reduce our infant death rate. At the present time of dearth and war the mismanagement of breast-feeding, with its resulting waste of food wealth and life, is a matter of national concern. Every doctor and nurse who has the responsibility of advising and assisting mothers in breast-feeding ought to urge its continuation wherever possible and as long as possible, and give their best thought and effort to overcome any difficulties that may arise. They should pause and think more than twice before they recommend weaning in the first month or two of life.

ULCERO-MEMBRANOUS STOMATITIS

THREE ATYPICAL CASES

BY

Squadron Leader T. CRADOCK HENRY,
M.R.C.S., L.D.S.

An investigation of 90 cases of ulcero-membranous stomatitis was recently undertaken, and of these, 87 were, on clinical and bacteriological evidence, classified as Vincent's disorder, while 3, which were atypical, form the basis of this paper.

Atypical Forms in the Literature

Reports in medical literature tend to show that atypical forms of ulcerative stomatitis are not uncommon ; they occur sporadically, sometimes in association with other diseases and sometimes alone. In most cases the condition bears a certain superficial resemblance to Vincent's infection, but the clinical course is usually different, as the chief features emphasized are the degree of toxaemia, the prevalence of complications, and the mortality.

In a rather different category is a group of cases showing a variety of skin lesions with similar manifestations in the mouth. Of these the most important are pemphigus vulgaris, erythema multiforme, and dermatitis herpetiformis. Up to recent times these cases were diagnosed on the clinical findings, but few attempts seem to have been made to investigate the bacteriology or the blood picture. Pemphigus is pre-eminently the disease in which most difficulty is encountered in making a differential diagnosis, as the bullae may first appear either on the lips or in the mouth. Matis (1940), in describing 5 cases of pemphigus in which the lesions were entirely confined to the mouth, points out that the diagnosis rested on the identification of the typical bulla, which ruptured in a few hours, and states: "Following rupture, the flaccid pellicle sloughs off, leaving a superficial ulcer, which promptly develops a marked secondary inflammatory reaction." Erythema multiforme, which also produces a bullous lesion in the mouth, may be another source of difficulty, but again the diagnosis must rest on the discovery of the typical lesion.

In describing cases of atypical ulcerative stomatitis some authors have applied the term "streptococcal." Costello (1931) reports a number of cases of coincident sore throat and sore mouth in children. The lesion in the mouth was apparently pustular in type, not dissimilar to the bullae of pemphigus, and on rupture it left behind a superficial ulcer. Culture from the contents of these lesions gave an almost pure growth of haemolytic streptococci. Similarly, Mead (1932) gives an account of several cases of alleged streptococcal stomatitis in which the clinical features were mainly those of an acute marginal gingivitis. Culture from these cases usually resulted in a mixed growth of *Str. viridans* and *Staph. aureus*. In none of them, however, was the condition reminiscent of ulcero-membranous stomatitis in the full clinical sense of the term, nor were any of the patients seriously incapacitated by the disease.

A very different disorder was recently described by Walton and others (1941) in which the severity of the local condition, ulcero-membranous in type, was completely overshadowed by the alarming prostration and acute illness of the patient. The clinical features of the 3 cases bear such a striking resemblance to those of Walton that it is felt they may belong to the same group. They have in common the following characteristics: (1) The patients were acutely ill, with the manifestation locally of a wide-spread ulcerative stomatitis, associated with a conjunctivitis. (2) Swabs from the mouth failed to reveal the presence of Vincent's organisms in significant quantity, but streptococci were grown on culture. In Walton's cases the organism was believed to be a streptococcus of the *faecalis* type. (3) There was no response to sulphanilamide or sulphapyridine therapy, but the patients appeared to improve after blood transfusion.

The histories of the 3 atypical cases in the present series are as follows:

Case I

An A.C.2 aged 19 was admitted to hospital on May 17, 1940. Seven days previously he had had a slight sore throat, which had abated until, two days before admission, it had recrudesced simultaneously with the appearance of a sore mouth.

When first seen he was obviously very ill; cyanosis and dyspnoea were present, and the temperature was 104° F. and the pulse rate 140. He complained of dysphagia, and trismus had developed. The mucous membrane of the lips, gingiva, and soft palate was covered with a whitish-grey tenacious exudate, which on removal revealed shallow ulcers that bled freely. Haemorrhage, in fact, was observed from all the gingival margin, which was grossly hypertrophic. Smears taken from the mouth showed a few Vincent's organisms, together with large numbers of Gram-positive cocci. Aerobic culture gave an almost pure growth of haemolytic streptococci. The Wassermann reaction was negative. A general examination revealed no gross abnormality except the presence of moist rales at the left base. Sulphanilamide was given in preference to sulphapyridine, and the patient received an initial 24-hour dosage of 8 g.

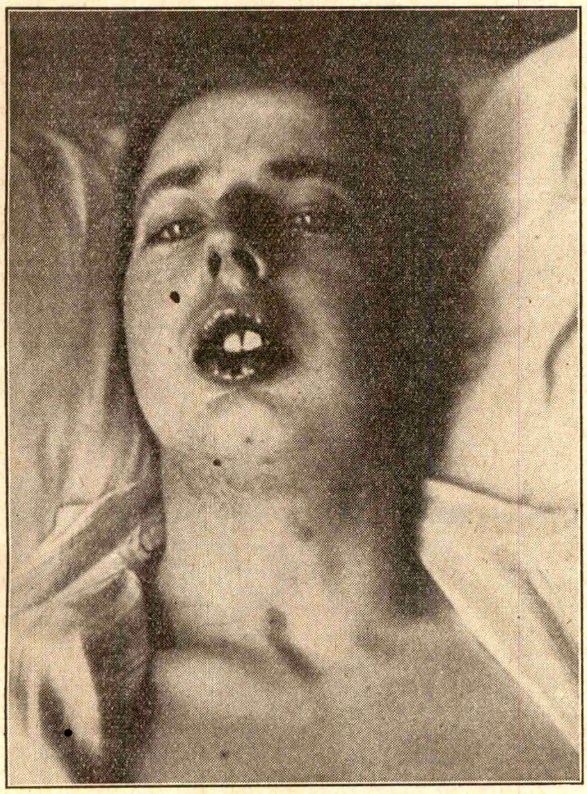

FIG. 1.—Case I. Acute phase 5 days after admission, showing bilateral conjunctivitis and blepharitis; oedema, bullae, and crusting of lips; and skin lesion. In the collar area the vesiculation, erythematous base, and central red spot can be seen.

The following day he seemed to have improved slightly and the temperature had fallen to 100° F. A skin lesion was now present; this took the form of a vesicular eruption on an erythematous base, and was first noticed on the left forearm and in the collar area. In addition conjunctivitis appeared, and a sticky discharge covered the lid margins (Fig. 1). On the fourth day a tentative diagnosis of pemphigus was made, and it was proposed to continue the sulphanilamide for a full course. The patient's general condition had begun to show a rapid deterioration; the temperature had risen again, he was taking little nourishment, and the prostration was alarming. It was therefore decided to try the effect of a blood transfusion, and 500 c.cm. of fresh citrated blood was administered. At this time the skin lesion had reached its maximum extent, and bullae were present on the arms, legs, and chest, with one on the glans penis. Smears from the mouth failed to reveal Vincent's organisms, and culture gave a heavy growth of haemolytic streptococci, both α and β. The white cell count was 13,000 per c.mm.

The following morning the patient was greatly improved, and during the next 4 days the temperature showed a gradual return to normal. On May 24 the chest was radiographed and evidence was found of a resolving bilateral bronchopneumonia. Blood culture from a specimen taken on May 19 was sterile, as was a culture from the exudate in one of the bullae. Further smears from the mouth again showed the presence of Gram-positive cocci, and culture gave an almost pure growth of haemolytic streptococci.

From about this time onwards the skin lesion started to fade and in the mouth the membrane began to separate, leaving behind a painful haemorrhagic surface. Oedema of the lips was still manifest as late as May 27 and the ulceration appeared tardy in healing. It was not until June 5 that the mouth lesion was completely resolved.

The patient was discharged from hospital on June 21, and so far as can be ascertained no other attacks have occurred.

Case II

A corporal aged 19 was admitted to hospital on Oct. 20, 1940, having been transferred from his local sick-quarters. For 5 days he had had a sore mouth, which had ulcerated 2 days before his admission. On the day previously his eyes became sore and he had awakened in the morning with the lids stuck together by discharge. He gave a previous history of having had a similar attack, in which a skin lesion had followed. This attack had never been satisfactorily diagnosed, but it was apparent that he had been gravely ill.

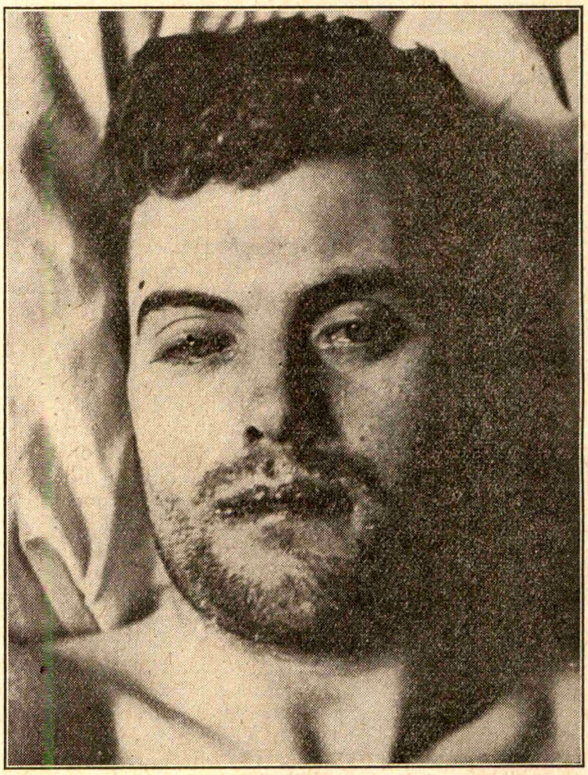

FIG. 2.—Case II. Acute phase 8 days after admission, showing ulceration and formation of small bullae on lips, and bilateral conjunctivitis, with some discharge present on lid margin.

On examination the patient appeared restless and anxious; he was of a greyish pallor and slightly dyspnoeic, but no abnormal signs were present in the heart or lungs. The temperature was 100° F. and the pulse 120. A purulent conjunctivitis was evident, but no skin lesion except a residual staining from the previous attack. Inspection of the mouth showed an extensive ulceration, with a thick dirty white exudate, membranous in character. This covered the gingiva and the mucous membrane of the floor of the mouth, the cheeks, and palate. The lips were only slightly involved, but were oedematous. The white cell count was 12,000 per c.mm., with 74% polymorphs, and a swab from the mouth revealed a few Vincent's organisms, culture giving a mixed growth of haemolytic streptococci, pneumococci, and *M. catarrhalis*. The Wassermann reaction was negative.

The patient was placed on a full course of sulphanilamide, with an initial 24-hour dosage of 8 g. The drug was continued for 6 days. He showed little improvement; the temperature was gradually rising and toxaemia was evident. A skin lesion appeared on the third day after admission, being first detected on the back in the scapular region and on both arms. The lesion was tender to pressure and similar in appearance to erythema multiforme.

On Oct. 24 the temperature reached 103.5° F., the pulse was thready, and the general condition appeared alarming. Prostration was evident; the patient was unable to take nourishment because of dysphagia, and oedema of the soft palate caused great distress. The skin lesion had extended, and was present on the buttocks, the lower limbs, and the dorsum of the penis. Two of the lesions had central vesiculation, which does not show in the photograph (Fig. 3). The white cell count was 7,800 per c.mm. A further swab from the mouth was identical with the first.

On the basis of the dramatic improvement that had taken place in Case I, a transfusion of 500 c.cm. of fresh citrated blood was given by slow drip. A rigor occurred shortly after the transfusion had begun, but despite this the procedure was completed.

On Oct. 25 the patient both looked and felt better; the temperature had fallen to 100° F. and the oedema of the soft palate was less. In the interim period mild non-specific treatment had been given to the mouth, which had shown a gradual improvement; the membrane had separated in places, leaving behind a shallow ulcer. The skin lesions began to fade, and by Oct. 30 had disappeared completely. Smears from the mouth taken on Oct. 26 and 30 failed to show the presence of Vincent's organisms, and culture on both occasions gave an almost pure growth of haemolytic streptococci. Swabs from the eye did not reveal any organisms, and the blood culture was negative. Figs. 2 and 3 illustrate the condition as it appeared 8 days after admission.

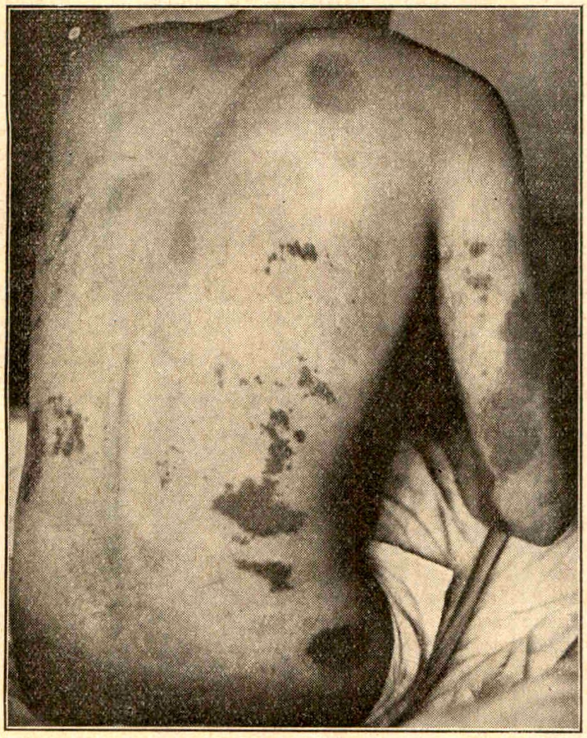

FIG. 3.—Case II. Eight days after admission. Old staining can be seen in large patches on the trunk, buttocks, and posterior aspect of upper arms. Recent purpuric lesions are mostly with limits of previous staining.

The patient showed continued improvement, and the temperature remained normal after Oct. 27. The mouth, however, was slow to heal, and it was not until Nov. 5 that all ulceration had ceased. The patient was discharged on Nov. 12.

Case III

This patient, aged 18, was admitted to hospital on June 27, 1941, as a transfer from his local sick-quarters, 5 days after the onset of a severe stomatitis, which had been diagnosed as Vincent's infection.

On examination he presented a severe ulcero-membranous stomatitis involving the gingiva, the mucous membrane of the cheeks, the lips, and the soft palate. There was a single bulla on the tip of the tongue. The membrane was tenacious and not easily separated, and was grey in colour. His lips were swollen, trismus was present, and he complained of dysphagia. The breath was not fetid. The patient's general condition was fair, but he looked toxic. The temperature was 103° F., the pulse rate 120, and the respirations 36; moist sounds were evident at the left base. He had an angular conjunctivitis, with filmy strands over the cornea. Smears taken from the mouth failed to reveal Vincent's organisms, and culture gave an almost pure growth of *Str. viridans*. A smear of the conjunctival exudate revealed a few pus cells and an occasional diphtheroid, but no other organisms. At this time the white cell count was 13,000 per c.mm.

Treatment during the next two days was mainly expectant, non-specific measures being applied locally. The patient's general condition, however, deteriorated, and as the clinical signs and a radiograph of the chest were compatible with a basal pneumonia, a course of sulphapyridine was started on June 29—30 g. in all. On July 4 the drug was withheld, but as the temperature still remained over 100° F., and on the experience in the previous two cases, a small transfusion of 350 c.cm. of fresh citrated blood was given. There was an evident improvement in the patient's general condition following the transfusion, but it was not so dramatic as in the first two cases.

Up to this time the mouth condition had remained more or less static, but by July 7 the membrane was beginning to separate, leaving behind shallow ulcers, which healed with great rapidity.

Further smears from the mouth had been taken, but on no occasion were Vincent's organisms seen, and culture gave an almost pure growth of *Str. viridans*. No skin lesion developed at any time. By July 17 the patient had improved considerably and his condition had ceased to cause any grave concern. The blood picture showed haemoglobin 94%, red cells 5,340,000 per c.mm., and white cells 5,800 per c.mm. The mouth, however, was still unhealed, although the conjunctivitis had practically disappeared. Cervical adenitis, which had been a pronounced feature in this case, was now nearly absent.

The ulceration in the mouth was healed by July 22. The temperature had remained normal since July 9, and the patient was eventually discharged from hospital on Aug. 7.

Discussion

Three cases of an atypical ulcerative stomatitis have been described which at first sight bore a strong resemblance to Vincent's infection of an acute and widespread type. Clinically, this resemblance was only superficial; for in each case purulent conjunctivitis was present, foetor oris was never marked, and two cases developed skin lesions. Toxaemia with prostration was considerable in all three, and they showed in common a failure of response to sulphanilamide but marked improvement after blood transfusion. That the lesions were not classical Vincent's stomatitis is confirmed by the bacteriological findings.

The oral lesions could be described as ulcero-membranous in character in each case, and with one exception bullae were not found in the mouth. In addition the stomatitis preceded the appearance of the skin lesion by some days. These two facts seem to indicate that, whatever the nature of the stomatitis, it was not a manifestation of pemphigus or other primary dermatological condition.

As has been seen from the case reports, the organism mainly isolated in culture from the oral lesions of these patients was a streptococcus. In Cases I and II it was haemolytic, often in almost pure culture, and in Case III of a non-haemolytic type. Unfortunately, a detailed pathological investigation was not pursued, since facilities were not then available. However, the consistent isolation of these organisms in culture, together with the absence of other significant organisms, is of interest, and it would appear profitable to speculate on the relation of the streptococcus to the clinical picture presented.

It is known that toxic manifestations, with high temperature, toxaemic cutaneous eruptions, purulent conjunctivitis, and syndromes of a like nature may arise from a localized streptococcal infection, and although it is not suggested that in the first two cases the haemolytic streptococcus was the sole causal agent, it is believed that its presence had very considerable influence on the clinical course of the disease. In Case III the streptococcus found was of a non-haemolytic variety, and it is noteworthy that in this case generalized skin lesions did not appear and, on the whole, toxic manifestations were less marked.

The fact that little response was obtained from the administration of sulphonamides in these cases would appear to absolve the streptococcus as the morbid factor, but cases of streptococcal infection are frequently seen in which no appreciable benefit has been obtained from this group of drugs, and, as has recently been shown, strains of haemolytic streptococci completely resistant to them do occur. Francis (1942) describes several cases of wound infection by a Group A Type 12 streptococcus resistant to sulphonamides, lack of inhibition of growth being demonstrable *in vitro*. This resistance is, however, not a specific type characteristic, and it seems likely that other types may, under suitable conditions, produce sulphonamide-resistant strains. However, quite apart from the possible presence of such a strain in these cases, the fact that a generalized toxaemic condition was well established lessened the clinical value of sulphonamide administration. Certainly, the problem becomes very different from one in which the streptococcus is proliferating in an open wound.

While it is realized that in these three cases there is not sufficient evidence to justify the conclusion that the streptococcus was the specific causative organism—in fact, a neurotropic virus might well be implicated—it is suggested that its presence influenced the clinical picture to a marked degree; and, although it is not possible to make a diagnosis until more is known of the condition, it is considered that this acute ulcerative stomatitis with its concomitant toxic syndrome constitutes a well-defined clinical entity.

Summary

In a series of 90 cases of ulcero-membranous stomatitis recently investigated 87 were classified as Vincent's disease. The remaining 3, which differed materially from the others, showed marked toxaemia and failed to respond to sulphanilamide and sulphapyridine; improvement, however, followed blood transfusion. In each of these 3 cases streptococci were isolated from the mouth lesions.

I wish to thank Wing Commander I. MacKay and Wing Commander K. Robson for their help and encouragement, and Squadron Leader R. Wynroe for the photography.

GROUP PSYCHOTHERAPY

BY

MAXWELL JONES, M.B., M.R.C.P.Ed., D.P.M.

Group treatment if effective would have a particular value in wartime, when there is a relative shortage of doctors and, potentially at least, an increase of patients with neurosis. The number of neurotic patients who can be adequately dealt with by one doctor varies according to the type of patient and the type of treatment practised by the therapist, but, in general, 25 to 30, with an average duration of stay in hospital of about six weeks, is a reasonable estimate.

The effort-syndrome unit at the hospital to which I am attached has 100 beds and comprises patients with various mild neurotic states, all of whom are carefully examined to exclude organic disease, and all of whom have fatigue as their main symptom. They show various anomalies of vegetative function such as palpitation, postural giddiness, labile blood pressure, tachypnoea, hyperventilation, frequent sighing, sweating of an emotional distribution, hot flushes, cramps, and paraesthesiae. This vegetative lability has frequently been present since childhood, and while individual psychotherapy may lessen psychic anxiety and effect personality change the somatic symptoms often remain very resistant to treatment.

Patients with effort intolerance were first treated here by the usual psychotherapeutic measures, in addition to the general psychiatric methods, an attempt being made to get at any major emotional factors which might help to explain the development of the patient's effort phobia. In the resulting discussion and explanation it was necessary to deal with the cardiac neurosis that was usually present. This necessitated some simple explanation of the physical accompaniments of an emotional state, but great difficulty was experienced in removing the patient's belief that he had heart disease, which was sometimes held with almost delusional intensity.

Another great difficulty was that patients did not come here seeking treatment: speaking generally, their main conflict was over Army service, which for one reason or another they disliked intensely. From contact with such men I came to the conclusion that their low morale was more satisfactorily combated by talking to them in groups than by individual interviews. One had the feeling—and this was endorsed by the nurses' observations—that in individual interviews the men fought shy of such a topic, but at night, after "lights out," would discuss freely their dislike of the Army, their grievances, and their desire for discharge, the last being amply justified because in their opinion they had heart disease, and so on. During such discussions a patient had ample opportunity for dramatizing his predicament, and there was no possible way for the other patients to verify his statements.

After two years of individual psychotherapy conducted under rather difficult conditions, as outlined above, influenced also by the need for doctors to deal with many more patients than is at present the case, it was decided to try a form of group therapy. The patients had been carefully selected and had approximately identical symptomatology: this made the problem much simpler than would usually be the case in a psychiatric ward. The treatment was tried on a group of 50 patients, the remaining 50 being given individual psychotherapy by other doctors. There were two main problems to be considered: the patient's attitude towards his symptoms, and the degree of group responsibility which he showed. These two aspects are best discussed separately.

Patients' Attitude towards Symptoms

As already stated, most of the men on arrival here had marked vegetative imbalance, which they interpreted as positive evidence of disease. A simple explanation of psychosomatic relationships did not appear to be sufficient to undermine this belief, and much more detailed instruction was indicated. The procedure adopted was to have three meetings a week at 9 a.m. on alternate days. The patients and doctor were seated comfortably, the whole atmosphere being completely informal. The junior nurses working on the wards sat at one end of the room. The talk lasted on an average 20 to 30 minutes, with a quarter of an hour at the end for open discussion. At first the talks covered a wide range of topics, including heredity, child psychiatry, the unconscious, propaganda, inferiority feelings, fatigue, relaxation, etc.; but it soon became clear that some definite system, whereby the education was more unified, was necessary. For this purpose I have found that the central nervous system is a suitable subject because it lends itself most easily to diagrammatic representation; thus, talks about the autonomic nervous system or different levels of consciousness as pure abstractions are quite beyond the average patient's comprehension, whereas the same subject taught with the use of charts or a model brain is capable of holding his attention and means something to him. For instance, the brain is explained to the group as functioning at three levels—the cortical, the thalamic, and the brain stem—which, functionally, represent consciousness and the peripheral nervous system, undifferentiated emotions, and control of visceral activity respectively. The peripheral nervous system and autonomic nervous system are then discussed in detail without, however, using medical terms or going into details of anatomy. The main point is that the men should have a rough idea of the function of the nervous system and its importance in adjusting the individual to his environment (the exterofective system of Cannon). The autonomic nervous system is dealt with in a similar way, its function in maintaining internal equilibrium being stressed. When the men appear to have grasped these two distinct concepts they are taught how activity or inhibition at any one level may affect the other levels—e.g., the toxic effects produced by alcohol in removing the inhibitory influence of the cortex, resulting in uncontrolled emotional behaviour; or the effects of consciously apprehended emotional experience upon the vegetative nervous system.

The justification for teaching such an over-simplified abnormal physiology rests in the need for giving the patient some more or less concrete conception of the meaning of "nerves." By actually pointing to nervous structures, represented diagrammatically or by a model brain, the men find that such an abstraction as nerves becomes a reality for them in just the same way as heart disease represents a reality. Moreover, they are always ready to listen to any intelligible discourse about their health, and by frequent reference to everyday evidences of vegetative instability this impression that nerves are a reality is readily strengthened. The whole atmosphere is that of a lecture to intelligent men on a subject of general interest to them. This academic atmosphere is heightened by the presence of the nurses in that they are credited with a certain educational level and prestige. The knowledge gained increases the patient's self-esteem and offsets the embarrassment which so often accompanies an insight into his neurosis: thus the man whose wife has always shown considerable concern regarding his supposed heart condition is able to relinquish this particular ailment provided he can give her some alternative explanation which does not involve the loss of too much self-esteem.

Merely transferring the emphasis from "heart" to "nerves" would be no great advance if it were not for the fact that nervousness cannot be divorced from the total personality. It is easy for anyone to understand that his feelings of fear and so on are part of himself—i.e., feelings and self are much the same thing. In this way the individual realizes that he has a certain responsibility in relation to his feelings and cannot sit back and expect the doctor to do everything, in the same way as he might do if he had heart trouble. The man's own initiative and resources are therefore called into play to find some solution for his problem. At this stage he may ask what action he can take if, having arrived at the point where he is prepared to do his utmost to meet the difficulty, no solution presents itself. Such a situation calls for the highest level of adaptive behaviour, the patient accepting that, temporarily at least, no solution can be found and that only a positive effort at adaptation will prevent a breakdown. The negative personality factors are stressed here—the resentments, prejudices, etc., which if present prevent any possibility of successful adaptation and are fertile soil for the growth of anxiety.

Group Responsibility

The majority of patients seen here have a very circumscribed outlook and are largely preoccupied with their own symptoms, emotional difficulties, and domestic situation; few have reflected on the reason for their conscription or have stopped to consider what they are fighting for. They seldom read newspapers and have only the vaguest conception of the extent and complexity of the war. To them there exist their home and a vague, ill-defined, unfriendly outside world. With no better sense of values than these it is not surprising that some men quite openly and shamelessly hope for nothing but their discharge from the Army.

Two methods might be employed to alter this state of mind: (1) an educational programme, the aim of which is to give the individual a balanced view of the whole world situation and an ability to appraise for himself the merits and demerits of the various systems of government, and to realize that for democracy to succeed a feeling of responsibility from each individual is demanded; (2) an exposition of conditions and restrictions which exist in some other countries and particularly in the occupied countries, with emphasis on the tragic fate of some subjugated peoples. So far only the former method has been employed here, and it is in this sphere that the nurses have been particularly useful. Their main object is to imbue the men with a feeling of group responsibility and make them realize that far more is at stake than simply their own future. A man who has openly made up his mind to get out of the Army if at all possible has not only his own conscience to consider but also the effect of his attitude on his contacts in hospital, the men at his unit, and, if he is discharged, his contacts at home. His usual plea is that he would be serving his country much better in his civilian capacity at a job for which he was properly trained rather than one where he is a misfit. Such a man has seldom stopped to reflect that practically no one in the Army regards soldiering as his natural vocation and that in a sense the great majority of soldiers are doing work less efficiently than that for which they were, from choice and aptitude, trained in peacetime. The nurse attempts to make him become conscious of the fact that his attitude of mind not only concerns himself but may have a marked influence for good or bad upon his contacts. Her approach must necessarily be an indirect one and occur quite naturally in a social situation. The patients are usually only too ready to discuss their family problems and show the nurses letters from their wives, which all too often are most unsuitable for a neurotic patient to receive, with over-anxious inquiries about their heart trouble and expressing the hope that they will soon be discharged from the Army, etc. The doctor and nurse have to try and offset this damaging home influence and substitute a more realistic outlook. In general the men lack real beliefs, although most of them are convinced that their only salvation lies in a return to a circumscribed existence where they hope to escape from the awareness of world problems which they cannot understand and for which they feel no personal responsibility. The nurse first tries to improve the man's self-regard by getting him to talk about his past work and successes and, having established rapport, tries to arouse his interest in some activity within the Army. General reading is encouraged, particularly periodicals, because the more serious articles give a much greater amount of information than the daily papers.

These measures may appear to be so simple and obvious as to lack therapeutic value, but it must be borne in mind that we are not concerned with the doctor's analytic approach to the problem of morale but with the simple methods which nurses can apply. It would appear undesirable that the physician should himself be too closely identified with this problem, for by so doing he might endanger his privileged position as a doctor.

Summary and Conclusions

During the last few months group therapy has been given to a group of 50 patients with effort syndrome. No follow-up figures are yet available, so that any discussion of results is premature. There is no doubt, however, that simple talks on health problems bearing on their illnesses prove of great interest and value to the men. The danger of fostering hypochondriasis is fully realized, but a hypochondriacal attitude towards their symptoms was already present in these patients on admission to hospital and the various vegetative symptoms had been interpreted as evidence of disease, particularly heart disease. It was found comparatively easy to alter the conception of heart disease to one of "nerves." In order to do so, however, it was essential to avoid, so far as was possible, abstractions such as talks on emotions, the unconscious, belief, etc., and to build up instead an apparently real structure round the conceptions of the central nervous system, which was best done by the use of a model brain, charts showing the nervous system, etc. This led on to discussions on emotions and bodily changes, always relating events to actual change in the nervous system. The next step was to correlate vegetative symptoms, feelings, and self, which, if accepted, meant the adoption by the patient of a personal responsibility in relation to his illness. Finally, emotional difficulties and personality problems were discussed as being the level at which disequilibrium in the nervous system could best be tackled.

It has been found in practice that the men adopt these new ideas with surprising readiness, and that among themselves and in conversation with the nursing staff there is much less tendency to discuss their symptoms than previously. Further, the preoccupation with heart disease has almost disappeared from the wards, and the number of men returning for Army duty is higher than at any time since the unit started two and a half years ago.

Complementary to the group treatment is the employment of the nursing staff to give individual attention to patients, and particularly to support the doctors' views regarding the patients' symptoms and to develop a sense of group responsibility. This must be largely an individual matter depending upon the ability and beliefs of the particular nurse, but an attempt has been made to indicate in a general way how the nurses have been encouraged to tackle these problems.

Impressionistically, the results have so far been better than with any previous method. There is no doubt that the atmosphere in the wards has improved enormously and the patients are far less preoccupied with their symptoms.

I would like to thank Dr. W. S. Maclay for permission to publish these results and for every possible encouragement.

THE SEDIMENTATION RATE AND THE SEDIMENTIN INDEX*

BY

B. L. DELLA VIDA, M.D.Rome

Assistant Pathologist, the Royal Hospital, Wolverhampton

Since Fahraeus (1921) and Westergren (1920) investigated the phenomenon of the sedimentation of the red cells (E.S.R.) and first gave details of a technique for measuring its rate an extensive literature has accumulated on the subject. Much has been learned of the factors involved in the phenomenon, though its ultimate cause remains obscure, and of its implications in clinical medicine. Some half-dozen different techniques have been recommended for its investigation; this is unfortunate, since it is now abundantly clear that to be comparable results must be obtained under identical conditions. The estimation of the E.S.R. already occupies an important place in clinical pathology, but there is still not even general agreement as to the best means of its expression. Thus the Westergren E.S.R. estimation refers to mm. fall in one hour, the Linzenmeier (1920) method reports the number of minutes taken for the red-cell column to reach a certain mark, and the Rourke and Ernstene (1930) technique records results as mm. fall per minute. The applications and implications of the E.S.R. in clinical medicine are far from being fully understood; the adoption of a common technique and mode of expression of results, such as to make the figures obtained by different workers comparable, would do much towards bringing about a fuller understanding.

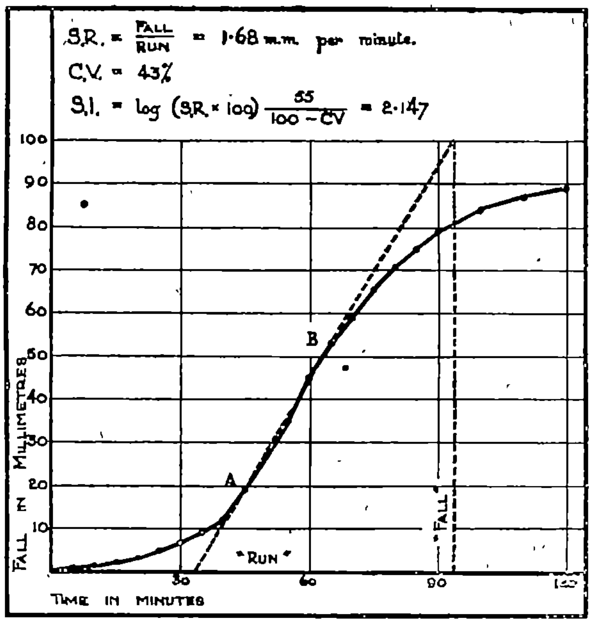

FIG. 1

Excellent reviews are available by Ham and Curtis (1938) and others on the technical aspects and by Reichel *et al.* (1936) and others on the clinical applications of the E.S.R. In the present communication it is proposed to deal only with certain facts, already well known, but of which the importance in the estimation and expression of the E.S.R. has not perhaps been fully recognized.

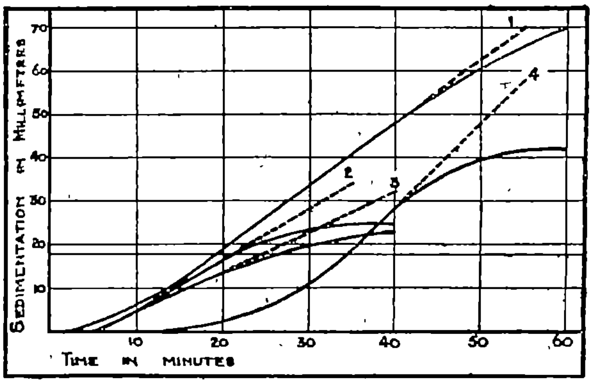

FIG. 2.—Sedimentation curves of samples of the same blood specimen by method of (1) Westergren, (2) Cutler, (3) Linzenmeier, (4) Rourke-Ernstene or Wintrobe-Landsberg. Erythrocyte cell volume 42.8%. [Graph drawn from Ham and Curtis's *Medicine* (1938).]

The rate of the sedimentation of the red cells depends primarily on their clumping. The nature of the agent responsible for this clumping is obscure, but it is accepted that it is a factor resident in the plasma; this, following Day (1940), may be spoken of as "sedimentin." The purpose of the estimation of the E.S.R. is to find an expression of the activity of this factor. The phenomenon of sedimentation is governed by certain physical laws. As shown in Fig. 1 it follows three phases. First, from the zero point at the top of the column the red cells begin to aggregate and to move towards the bottom of the tube, increasing their speed until at point A the second stage, the "period of constant fall," is reached. In the third phase, at point B, "packing" intervenes and the rate of fall is slowed down until it is reduced to *nil* and the sedimentation is complete.

If the various techniques commonly in use for the estimation of the E.S.R. be employed on the same specimen of blood and at the same time, it will be seen, as shown in Fig. 2, that not only the falls as mm. in one hour but also the maximal velocities of sedimentation are different.

Factors Influencing the Sedimentation Rate

Size and Position of Tubes.—Once the period of constant fall had been reached the speed of settling of the corpuscles would remain unchanged if "packing" did not intervene. Therefore from a theoretical point of view the height of the column of blood should be infinite. This is not feasible, but to ensure reliable readings the blood column should be as high as possible. A height of 100 mm. is sufficient, but the 200 mm. of the original Westergren apparatus is preferable. The diameter of the column should be more than 2.5 mm., to avoid the capillary action of the tube (Walton, 1933). The tube must be perfectly vertical, as very slight inclination profoundly affects the rate of fall (Ponder, 1925).

Red Cell Volume.—The sedimentation phenomenon is due to the influence of plasma "sedimentin" on the red cells; therefore, in the presence of anaemia there will be a relative increase of "sedimentin" to each red cell present: Fig. 3 shows the effect of varying the concentration of the red cells in the same plasma. It shows that the more anaemic is the blood the higher is the sedimentation rate, and this not only if expressed as fall in one hour but also as fall per minute during the period of constant fall (Rourke and Ernstene, 1930; Schuster, 1938).

---

* Paper read before the summer meeting of the Association of Clinical Pathologists, June 27, 1942.

Anticoagulants.—The original Westergren technique and several of those described later employ as anticoagulants solutions of varying strength of sodium citrate. More recent techniques use heparin, dry potassium oxalate, or oxalate mixtures. The experiments of Ham and Curtis and others prove that only dry oxalate mixtures as recommended by Heller and Paul (1934) and heparin ensure comparable results and at the same time prevent shrinkage of the red cells, thus allowing a correct reading of the corpuscular volume.

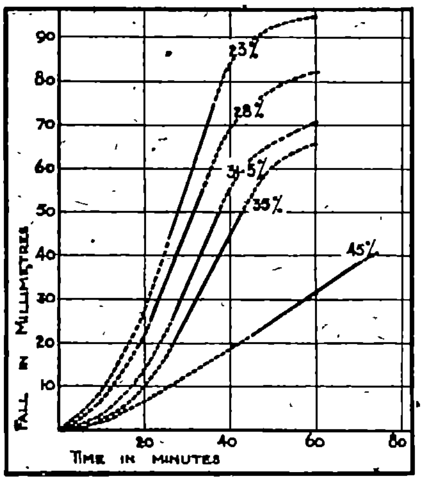

FIG. 3.—Showing the effect of varying the concentration of red cells in the same plasma. 45% = 0.70 mm. a minute; 35% = 1.97 mm.; 31.5% = 2.53 mm.; 28% = 2.64 mm.; 23% = 3.10 mm.

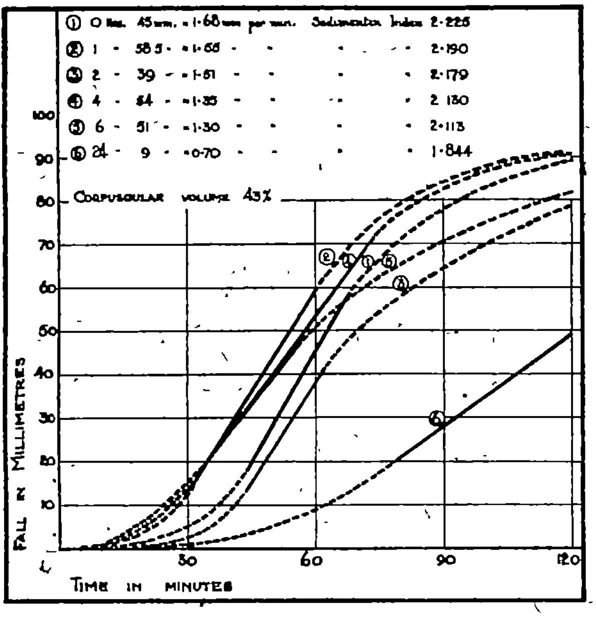

FIG. 4.—Graph showing progressive reduction with age of specimen of blood.

Time.—The E.S.R. is a labile phenomenon showing progressive reduction with the age of the specimen. Fig. 4 shows that the reduction is small up to from 4½ to 5 hours from the taking of the sample; thereafter it is rapid, until after from 24 to 48 hours the phenomenon has almost completely disappeared. The lability of the phenomenon has been shown by Day (1939) to be due to loss by the red cells, on standing, of susceptibility to clumping. The "sedimentin" activity of the plasma remains unimpaired for long periods. From this it follows that the "sedimentin" activity of the plasma of samples of blood older than 6 hours may be estimated with reasonable accuracy by combining the plasma with washed red cells from a fresh sample. Fig. 4 further serves to show that the crude reading of fall by mm. in one hour is not reliable, and that the figure subject to least variation is that expressing the fall over the period during which this is constant.

Temperature.—Variation in the ambient temperature considerably influences the sedimentation rate, but at the temperature of any ordinary laboratory this is not likely to be an important factor.

Size of Red Cells.—This appears to affect the sedimentation rate, but the variations so introduced are so small as to be of no practical importance.

Technique Recommended

From a vein in the antecubital fossa 5 c.cm. of blood is drawn into a centrifuge tube containing 10 mg. of the Heller and Paul dry oxalate mixture (4 mg. of potassium oxalate and 6 mg. of ammonium oxalate). A sedimentation tube of the Westergren type is filled to the 200-mm. mark; at the same time a haematocrit tube is spun down to ascertain the corpuscular volume. If the blood has been standing for some time (never more than 4 hours) it is gently but thoroughly mixed before setting up. The rate of fall is observed until the period of constant fall has been reached or until "packing" begins. The rate of fall can be observed either every 5 to 10 minutes or, as is desirable in the case of samples showing high sedimentation rates, by recording the time at every 5-mm. fall.

Finding the Sedimentation Rate and Sedimentin Index

The figures obtained by the observation are plotted on graph paper and the straight line expressing the period of constant fall is prolonged at both ends (Fig. 1). The sedimentation rate is given by the formula S.R. = $\frac{\text{Fall}}{\text{Run}}$ and expressed as mm. fall per minute. With experience it is easy to determine the period of constant fall from the figures alone without plotting. The normal range of the S.R. is from 0.05 mm. a minute or less up to 0.25 mm. a minute. The observed S.R. will in the presence of anaemia require correction for corpuscular volume. This may be done by means of the tables of Rourke and Ernstene. It can be done even more conveniently by making use of the sedimentin index suggested by Day.

The sedimentin index is the logarithm of the figure expressing the rate of fall over 100 minutes calculated on the basis of the constant fall per minute. Correction for anaemia may be made by simple arithmetical proportion, taking 45% as the normal corpuscular volume (C.V.), according to the formula,

$$\text{S.I.} = \log.\ (\text{S.R.} \times 100)\ \frac{55}{100 - \text{C.V.}};$$

and for correcting the observed sedimentation rate,

$$\text{S.R. (corrected)} = \frac{\text{antilog. S.I.}}{100}.$$

The normal range of the S.I. is from 0.5 or less to 1.4. Figures above 1.5 must be regarded with suspicion, but it must be borne in mind that a common cold may produce an increase of the S.I. up to 1.5 or thereabout.

The correction for an abnormal corpuscular volume is valid only in the presence of anaemia. In the case of bloods with C.V. higher than normal (polycythaemia, haemoconcentration due to shock, etc.), other factors, such as viscosity, enter into play and produce a retardation of the sedimentation not accountable for by the increased number of red cells. In these cases it is advisable to adjust the C.V. to a figure of 45% or slightly less before the estimation of the sedimentation rate.

Summary

For estimations of the sedimentation rate of the red cells to be comparable it is essential that they be performed by an identical technique and expressed in the same manner.

It is recommended: (1) That 5 c.cm. of blood be withdrawn by venepuncture into a dry mixture of 4 mg. of potassium and 6 mg. of ammonium oxalate. (2) That the estimation be made within four hours of withdrawal of the blood. If this is not possible the plasma may be separated and put up against fresh washed red cells. (3) That a tube giving a blood column of 200 mm. in height and at least 2.5 mm. in diameter be used and that this be set up in a strictly vertical position. (4) That only the rate of fall during the period of constant fall be considered in the expression of results. (5) That correction be

made for anaemia. This may most conveniently be done by using the sedimentin index of Day.

I wish to express my sincere thanks to Dr. S. C. Dyke, director of the department, for his advice and much helpful criticism; and to A. W. Farmer for his technical assistance.

THE PREPARATION OF HOUSE-DUST EXTRACTS

BY

CHARLES SUTHERLAND, M.B., M.R.C.P., F.R.A.C.P.

Major, R.A.M.C.; Physician to Asthma Clinic, Alfred Hospital, Melbourne, Australia

Although hypersensitiveness to house dust occurs quite commonly and is an important factor in producing symptoms—e.g., in asthmatics and some types of chronic bronchitis—its existence is often completely missed by clinicians, partly because many of the extracts produced commercially for testing and treatment are either feeble or inert. The incidence and significance of this form of allergy will be properly assessed, therefore, only when potent and stable extracts become readily available. Such extracts should be so potent that they produce a large, irregular, itching wheal when used in a "scratch" test, and they should be quite inert when similarly tested on the skin of normal individuals. The "scratch" test offers a ready means of comparing the activity of different fractions isolated from dust, and was used in preference to the intradermal method throughout this work.

Since Cooke (*J. Immunol.*, 1922, **7**, 147) first demonstrated that some ingredient in house dust acted as an allergen, many attempts have been made to establish its identity, but this still remains a mystery. At first it was assumed that the activity might be simply due to a mixture of known allergens, but subsequent work has made this seem unlikely, and it appears that it originates from a single substance. Investigations made during the past two years suggested that this active substance might be adsorbed on to the particles of dust, and it was found that N/100 ammonia, which is often used in eluting adsorbed substances, did, in fact, bring the active fraction readily into the aqueous solution. Samples of dust from different houses vary considerably in activity, but by the scratch test it is easy to select a satisfactory sample. Five hundred grammes of this is just wetted with N/100 ammonia and left for 24 hours. It is important not to add excess of the fluid. The mass is then wrapped in cloth and squeezed in a powerful press, and the muddy fluid so obtained is filtered through paper and the pad of a Seitz filter until a clear yellowish filtrate is obtained. Sodium benzoate (20 g. per litre) is now added, and this dissolves readily. Hydrochloric acid (1:5) is then gradually added until the mixture becomes just acid to Congo red. A very finely divided precipitate of benzoic acid appears, and after 12 to 24 hours this is filtered off in a Buchner filter and sucked as dry as possible. Much of the active substance is held in an adsorbed form in this mass of benzoic acid, and it is readily released when the benzoic acid is dissolved in acetone. An amorphous precipitate remains, and is removed by centrifugalization. It is washed repeatedly in acetone and finally in dry ether and allowed to dry. This brownish amorphous powder shows great activity and appears to provide an ideal test reagent, as it is quite inert when tested on "control" normal individuals. This method of adsorption does not remove the whole of the active substance from solution, so it is usually worth while to neutralize the filtrate and to repeat the process of precipitating benzoic acid at least once.

Samples prepared six months ago have remained very potent, but it is too early yet to decide on the keeping properties of the substance. It is of interest that Dr. C. Rimington of the National Institute for Medical Research, Hampstead, who carried out preliminary tests on a sample, reported that it appeared to be largely carbohydrate in nature and failed to give the usual reactions for proteins. If subsequent tests with purer samples confirm this they may throw a new light on the nature of allergens.

Tests on 100 asthmatic soldiers show that roughly 80% react strongly, and in 20 cases treatment by desensitization with a 1% solution produced spectacular improvement in almost every instance. Initial subcutaneous doses as small as 0.05 c.cm. produced marked swelling, redness, and itching within half an hour, but after a dozen weekly doses of increasing quantity even ten times the initial dose often produced little reaction, and this increase in tolerance was usually associated with a considerable lessening of the symptoms.

Exigencies of war have prevented further work on this substance at present, but the preliminary results have been so interesting that a note on this incomplete work seemed justifiable.

I wish to thank Prof. D. C. Harrison of the Department of Biochemistry, Queen's University, Belfast, for much helpful advice and hospitality, Dr. Cope for advice on the method of adsorption, Mr. W. Buick of Queen's University for much technical assistance, and Dr. Rimington for carrying out the preliminary biochemical tests.

Medical Memoranda

Subdiaphragmatic Collection of Bile following a Perforating Chest Wound

This case presents some unusual features which make it worthy of record.

CASE REPORT

The patient, a woman aged 36, sustained a penetrating chest wound from a bomb fragment on Sept. 8, 1940. She was transferred to our care two days later, an ill woman, cyanosed and dyspnoeic, with a temperature of 98.8°, pulse 92, and respirations 26. There was a small puncture wound on the right side of the chest in the mid-axillary line at the level of the eighth space. Movements of this side of the chest were poor, and there was a small area of dullness and diminished air entry at the right lung base. The abdomen was distended and rigid, and tender down the right side, especially in the hypochondrium. A radiograph of the chest showed a small opacity at the right base. A provisional diagnosis of pneumonitis and probable liver injury was made, and a blood transfusion and oxygen through a B.L.B. mask were given. The following day the signs, including a friction rub, suggested consolidation or haematoma in the right lung. Sulphapyridine was started in full doses. During the next few days the patient remained ill, with temperature 99°, pulse 100, and respirations 30, the main symptoms being a feeling of malaise, persistent abdominal pain, and an irritable cough, while the chief signs were dullness on the right side of the chest, which had gradually increased, with a correspondingly diminished air entry. At this time her conjunctivae were stained yellow and the urine contained bile. Further radiographs of the chest taken on Sept. 18, 8 days after admission, revealed what appeared to be an intrapleural collection of fluid, with a raised right diaphragm. Accordingly, on the same day a diagnostic puncture through the eighth space in the posterior axillary line was done; this yielded 20 c.cm. of sterile bile. The following day a further 100 c.cm. was withdrawn. Radiographs then showed the diaphragm to be considerably lower. After the second puncture the patient steadily improved, and radiographs taken at the end of October, about 8 weeks after admission, showed the diaphragm in normal position and a small bomb fragment situated in the centre of the liver area.

It was concluded that the missile had traversed the lower part of the lung, giving rise to the signs on admission, and after piercing the diaphragm had lodged in the liver. Following this liver injury an extravasation of bile had collected below the diaphragm, probably over the bare area. The exploratory puncture, although made in the eighth space, had gone through the pushed-up diaphragm into the subphrenic collection.

Commentary.—The main points of interest in this case are: (*a*) the difficulty in making an early accurate diagnosis; (*b*) the limitation of a large collection of bile to the subphrenic area;

and (c) the fact that this collection remained sterile. We believe that conservative treatment is correct in this type of case and that operative measures should be undertaken only if infection supervenes.

B. WOOD, M.B., B.S.

Shock Treatment in Psychosis complicating Pregnancy

The beneficial effect of shock therapy in the treatment of the emotional mental disorders is now so firmly established that any possible contraindications should be critically examined before deciding to withhold treatment. Several conditions which were formerly considered to be a bar to shock treatment have since been found to involve very little risk. A consideration of the patient's age, for example, is not now regarded as important, and patients of 70 to 80 and children of 3 years have been successfully treated with induced convulsions (Hemphill and Walter, 1941).

Provided they are well compensated, cardiovascular disorders are not serious obstacles, even in cases of auricular fibrillation (Good, 1940). In fact, both cardiazol and electric convulsions act as cardiac stimulants, with apparent benefit in cases of circulatory asthenia and low blood pressure. But so far as I am aware, little mention has been made in the literature regarding the use of shock therapy in the mental disorders arising during pregnancy. Although such disorders are relatively uncommon, it is possible that in some quarters the pregnant state is thought to be a contraindication to shock therapy. The result in the following case, however, suggests that in suitable patients the treatment is fully justified and entirely harmless.

The stress of pregnancy may precipitate a mental breakdown in predisposed individuals, usually a state of depression, but as a rule the prognosis is good when mental disorders occur before the fourth month. If they appear later they tend to become increasingly severe until the birth of the child, when they usually disappear. In the late case shock therapy would be worth while if only to enable the child to be born at home instead of in a mental hospital, provided there are no risks to the mother or the child. The first consideration, however, is the possible risk of precipitating a miscarriage. But this appears unlikely when one thinks of the number of epileptic women who have fits during pregnancy with no untoward results. Goldstein *et al.* (1941) state that a review of the literature indicates that epilepsy does not influence pregnancy unfavourably other than by predisposing to injury from falls. (The spasms of epilepsy occur only in voluntary muscles.) Those workers also report the case of a schizophrenic, 3½ months pregnant, who was given 13 cardiazol seizures and insulin shock treatment for 13 days with no harmful effects on the pregnancy. They conclude that convulsive or insulin treatment is justifiable in pregnant women because of the apparent harmlessness of convulsive seizures due to these drugs and to epilepsy.

The following description of a similar case would seem to support the above conclusion.

CASE REPORT

The patient, a married woman aged 23, was admitted to Wadsley Mental Hospital on March 7, 1941, as a voluntary patient suffering from melancholia of pregnancy. There was no history of mental disorder, although she had had a child 3 years previously, but it was stated that her father was of nervous temperament. The second pregnancy, however, had given rise to considerable emotional stress owing to the failure of a herbal abortifacient.

On her admission the pregnancy was 4½ months advanced, and she was in a state of acute agitated melancholia, emotional and weeping, crying out that she was wicked and had done a grievous wrong. She felt that people were talking about her and that something terrible was about to happen to her. She was in good physical health. Her mental state showed no improvement during the first 5 weeks of her stay in hospital, and she was therefore given a course of electric convulsion therapy with a view to effecting her discharge from hospital before the birth of the child. She received 13 convulsive shocks during the ensuing six weeks, and there was a progressive improvement in her mental condition. She was discharged recovered on May 29, 11 weeks after admission, and a subsequent follow-up on March 4, 1942, found her in good mental health and with a healthy 7-months-old baby. The latter was born on Aug. 8, 1941, after a normal and easy confinement.

Reviews

HAEMATOLOGY

Diseases of the Blood and Atlas of Hematology. By Roy R. Kracke, M.D. Second edition, thoroughly revised, reset, and enlarged (Pp. 692; illustrated. 90s.) Philadelphia, Montreal, London: J. B. Lippincott Company.

This work, of which a second edition has appeared within the relatively brief space of four years, is a very satisfactory textbook of haematology, which is in no way too advanced for the practitioner or the postgraduate student. It gives an extremely well-balanced presentation of the subject, without over-stressing the rarities, which is the chief pitfall in this field. It is beautifully produced and clearly printed on a thin matt paper instead of the horrible heavy glossy stuff which American publishers so often use, and it weighs only 4 lb. Its only serious fault is the price, which is 90s. This works out at 22s. 6d. a lb. We may compare this with Piney's *Synopsis*, which works out at 16s. a lb., and Janet Vaughan's *Anaemias*, which works out at 6s. a lb. These differences do not seem reasonable in terms of weight of text. On the other hand Kracke provides 54 colour plates for 90s., Janet Vaughan 4 for 12s. 6d., and Piney 4 for 10s. 6d. It is therefore clear that what the buyer is paying for is colour plates. It seems very doubtful whether it is economical to bind expensive colour plates with text which rapidly goes out of date, for the cells of the body remain the same however much our opinions about them may change. Atlases of haematology, like those of ophthalmology, would be better published without text, and one of the post-war desiderata is an international atlas of haematology, with an agreed terminology, which would be kept up to date by a standing committee, and of which a pocket edition would be published for the student. Such a student's atlas, with an international demand numbered in tens of thousands, could probably be produced for a few shillings, and its existence would be an incentive to writers of textbooks of haematology to describe the patient rather than the blood picture. For (*pace* some professors of medicine) the more we know about diseases and the more we can describe them in physiological terms, as we can the diseases of the blood, the less interesting they become to read about. No one can imagine "Kracke," or any other modern textbook of haematology, being treasured like "Trousseau" or "Osler" or read for its own interest a hundred years hence. Perhaps this is inevitable, and the textbooks of the future must be as dull and matter-of-fact as accounts of entropy or integral calculus. But in the meantime some of us feel that the drama of haematology still awaits its inspired author.

SCHIZOPHRENIA

Schizophrenia: The Cinderella of Psychiatry. By Reg. S. Ellery, M.D., F.R.A.C.P. (Pp. 170. 12s. 6d.) Sydney: Australasian Medical Publishing Co., Ltd. 1941.

This is not a textbook but an essay expressing the opinions of the author without reference to the work of others. Some may be put off by the great exuberance of language, for he delights in words and loves to juggle with them. Others may be put off by his undoubted predilection for Marxian principles. Nevertheless, the reader should not be put off; for Dr. Ellery does know all about schizophrenia, and gives a very good description of all aspects of the disease.

It may be that he accepts the promise of the new forms of shock therapy a little too optimistically, but he rightly states that they are the only kinds of treatment which have raised the expectation of remission or recovery above the average of "natural remissions" and have changed the ultimate prognosis of inevitable dementia to one of guarded hope for some sort of adjustment to life, even though it may be at a humble level. He discusses the question of prevention and seems to think that this lies chiefly in social reform, but in his computation of the evils of family life and the delinquencies of the average parent he rather overreaches himself. No doubt all the blows to the security and proper development of the child mentioned in the book may fall upon him at some time or other, though seldom all together; but no one has yet found a substitute for family life; for the child brought up by the State is not so happy or so normal as the one who is reared in the much-maligned home, and, in the Russian experiment, home life and the family have been and are being restored.

This is a book which should be read, for it is stimulating and informative and, above all, not too long.

AN AUSCULTATORY METHOD

The Pleuro-subpleural Zone. Its Clinical and Experimental Investigation and its Practical Importance in Chest Pathology. By J. Skládal. (Pp 104, illustrated 10s. 6d. net.) Cambridge The University Press 1942.

The reviewer recalls meeting this author some years ago when visiting a hospital in Prague. Dr. Skládal was discussing his method of auscultation by sudden expiration, producing gramophone records to support his argument. In spite of language difficulties sufficient impression was made on the reviewer, who promised himself a trial of the method on his return to England, but the intention was not fulfilled. Study of this small volume, with its extravagant claims put forward in no modest manner, has not caused him to regain enthusiasm either for the method itself or for the wide knowledge of "chest pathology" promised by its practice. The following extract from the conclusions will give a clue to his feelings of confusion:

> "In view of the polymorphism of corticopleural lesions, in order to allow for a clinical survey I consider it useful to distinguish between the true corticopleural syndrome, which may be simple or mixed, i.e. with lesions of rarefaction, and the pseudocortical syndrome. This principle of fundamental distinction has two advantages. On the one hand, it establishes a link connecting the cortical manifestations of pulmonary tuberculosis and unspecific pneumopathies; on the other hand, it stresses the importance of corticopleural lesions in daily practice. So the doctrinal elements of the true corticopleural syndrome bring some new and simple principles for use in everyday medicine."

All this is made easy by sudden expiration—"a method of sharp and relatively ample expiration, replacing the usual, noisy, and insufficiently elastic method of coughing, in auscultation and radioscopy of the lungs. So the different sounds are brought out more distinctly, and, radioscopically, various intrathoracic abnormalities may be revealed." But perhaps it is not so easy, after all, for this is what Dr. Skládal states in his introduction:

> "During an examination in 1932 by the method of sudden expiration I noticed an acoustic phenomenon which was so strange that not only my assistants but in subsequent demonstrations even very experienced doctors, did not dare to confirm my findings immediately—findings upon which I particularly insisted—namely, that instead of a single expiratory sound, a double sound is to heard."

There may well be something in what the author claims, but he will need to convey his findings in a clearer form than in this book to convince the average reader.

CHEMISTRY'S KEY POSITION

Out of the Test Tube By Harry N Holmes, Ph D Third edition, revised and expanded. (Pp 305; illustrated $3 00) New York. Emerson Books Inc

In this illuminating book it is shown that most modern achievements in the realm of material prosperity owe their existence to chemistry, and the author also demonstrates the key position occupied by chemistry in their inception. The treatment of the theme is not devoid of technicality, but the technical matter is presented in a form easily to be understood without a knowledge of chemistry. The influence of chemistry is traced through a great variety of different fields. These include anaesthetics and the curative properties of sulphanilamide; the cheapening of motor-car construction due to the unique effect of tungsten in the production of machine tools; the production of synthetic clothing, agricultural crops, industrial and other explosives; the artificially controlled quality of indoor atmospheres; and the transmutation of elements by atomic disintegration.

The book is full of entertaining information—historical, industrial, and statistical—and it includes the most recent scientific developments. A number of the developments here described, some of which are still in the tentative stage, may appear somewhat startling even to readers who are generally well informed; one such is the use of mercury vapour in the place of steam for a working engine producing 12,000 horse power. The author is possessed of a vivid imagination and he has the skill to write with such effect that a lively understanding is imparted to the reader. The book is written in a cheerful and vigorous style and is enlivened at times with a vein of humour. As an American Mr. Holmes has some pertinent remarks to make on the situation of the United States with reference to strategic raw materials and world power. All is done in very clear language, and the book may be recommended to students of chemistry as well as to the reading public.

Notes on Books

An American eye specialist, Dr. G. GRIFFIN LEWIS, has prepared a book which he names *The Ophthalmic Formulary* (Springfield, Illinois: Charles C. Thomas; $3.50). It is in effect a catalogue of numerous prescriptions for all sorts of eye diseases which are stated to be the favourite prescriptions of prominent oculists from all parts of the world. This is followed by a list of the medicines used in these prescriptions, with a short statement of the utility of each drug. No fewer than 27 prescriptions are set out for the treatment of a very ordinary surface disturbance, especially among children, namely blepharitis, but several are only variations of the same main line of treatment. Naturally one turned to the disease for which effective treatment is most imperative, ophthalmia neonatorum. For this disease only two prescriptions are given, and there is not a word on the new and most effective treatment by the use of sulphonamides. Since the introduction of these drugs the treatment of ophthalmia neonatorum has been completely revolutionized; they have rendered the local treatment of the disease almost unnecessary. It is the most wonderful advance in eye work known to many generations. The omission of any reference to this method of treatment of ophthalmia neonatorum in Dr. Griffin Lewis's book suggests that an early second edition is imperative.

The fourth volume of the *Proceedings of the Medico-Legal Society of Victoria* (Melbourne: Brown, Prior, Anderson) contains nine addresses and the reports of the discussions on them. These maintain the high standard which the society has reached in the past. The paper on medico-legal aspects of gas warfare surveys the administrative measures taken by the Commonwealth and State Governments; the medical aspects largely concern administration, and the legal aspects emphasize the need for statutory amendments. The setting-up is proposed of a special court to hear appeals by property owners aggrieved at the segregation of their premises after a gas attack. Sir Frederick Eggleston criticizes much of the present judicial structure, and particularly the methods of bringing expert witnesses before the court and their examination. The evergreen subject of quackery is illustrated by Dr. Stewart Cowen with a wealth of examples from personal experience, and the discussion is unusually rich. Dr. Anita Mühl deals with suggestibility in witnesses, Mr. P. D. Phillips with some aspects of workers' compensation legislation, Dr. Guy Springthorpe with the treatment of mental deficiency in Victoria, Mr. R. R. Sholl with coroners' inquests, Mr. R. N. Vroland with the future of the two professions, and Prof. G. A. Paton with the development of forensic medicine.

Into a booklet of 80 pages the modest and anonymous author of *Reminiscences and Reflections of a Medico on Land and Sea* (Nottingham: J. Clough and Son; 3s. 6d.) has compressed his life story. Son of a Congregational minister, he obtained his education largely through his own exertions, and became more than ordinarily qualified—M.D. (gold medallist), M.S., F.R.C.S.Ed., D.P.H., M.R.C.S. His surgical life was mostly as assistant to Mayo Robson, but he left that to take up more remunerative work in general practice. Later he became interested in public health problems, and having secured the D.P.H. of Oxford was ere long appointed M.O.H. of a county. He spent 25 years in that sphere of work, and resigned at the age of 60. In order to satisfy a *Wanderlust* he then went to sea as ship surgeon, and the second half of his reminiscences concerns his voyages round the world. In a most concise way he gives vignettes of the numerous places he visited, and the reviewer, from a similar experience, can add that "MEDICO'S" descriptions are wonderfully true. The only fault about this publication is its brevity. Now that the author has found his ability to write, one can hope that he will do so at greater length, for the story of a successful professional career must always be interesting and useful to medical men, if only from the point of view of "Go thou and do likewise."

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 5 1942

SAVING MEDICAL MAN-POWER

When war broke out a large number of medical men who were liable for service in the Territorial or reserve Forces were immediately called-up. The consequent adjustments in civilian practice were made without great difficulty, and a steady flow of practitioners to meet the further demands of the Fighting Services was maintained during the winter of 1939-40. After a short lull, when the Army was re-forming on its retirement from Dunkirk, expansion became so fast that the conflicting requirements of the Services, civil defence, and ordinary civilian practice became hard to balance. The Central Medical War Committee had the duty of supplying practitioners but not of determining how many were needed for each specific purpose. In fact, by letting the supply fall short of demand it did informally allocate, and the branches of the Services which were thus partly unserved, appreciating the difficulties, were at first not too insistent in their protests. The position was, however, unsatisfactory and potentially dangerous. The Central Medical War Committee therefore urged the Government to find some method of satisfying themselves and the profession that complaints of Service and institutional over-staffing were not justified, and that each Fighting Service had regard to the needs of the others and of the civilian population in determining its own medical establishment. The Robinson Committee was accordingly set up at the end of 1940 to make a rapid survey of the problem, and reported early in January, 1941. In March, 1941, the Ministry of Health issued a memorandum[1] urging upon local authorities and voluntary hospitals the need for economy in the manning of their medical staffs, and indicating that the Service Departments were making a similar review. It soon became apparent that the latter assurance was not enough, and, again at the instance of the Central Medical War Committee, the Government appointed a standing committee, known as the Medical Personnel (Priority) Committee, to secure the utmost economy in the employment of medical personnel in His Majesty's Forces and all civil establishments. The First and Second Interim Reports of this Committee have now been published (see p. 287), being an account of its work up to February, 1942.

The reports indicate that the Committee first addressed itself to the problem created by the very heavy demands of the Fighting Services. Their co-operation was readily given, and the situation was greatly eased by a reduction in these demands for the last half of 1941 by 50% in the case of the Navy, 40% for the Army, and 37% for the Air Force. If it were permissible to give the actual figures they would be found impressive. In order to secure further economies in static home units the establishment of Regional Priority Committees was recommended, and special stress was placed on the desirability of co-operative arrangements between A.A. and Balloon Commands. The Committee then turned its attention to the staffing of civilian hospitals. Here it found itself in some difficulty from lack of accurate information, but the Ministry of Health and the Department of Health for Scotland undertook the somewhat formidable task of gathering and collating it. As a result of a study of the data so obtained it was recommended that there should be increased transferability of staff as between one hospital and another and that the tenure of A posts by men should be uniformly restricted to six months. Mental hospitals were asked to supply a hundred men for the Services by reduction of their establishments. In order to maintain the flow of young practitioners from hospitals to the Services and prevent the replacement of the A men, whose calling up had been accelerated, by more senior residents, a cut was recommended in hospital establishments of A, B2, and B1 posts, as filled at August 1, 1941, amounting to 15% in London and 10% in other Regions. On the other hand, the importance of expediting the absorption of newly qualified men into A posts was stressed. Attention was also drawn to the need for scrutiny of pathological, research, and public health establishments, with a view to the release of young men. Hospital authorities are aware that further measures have been taken to speed up the recruitment of young practitioners since these reports were prepared.

There is evidence that the Ministry of Health and the Department of Health for Scotland have addressed themselves energetically to the difficult and uncongenial tasks imposed on them by the acceptance of these recommendations. If these steps had not been taken it is apparent that the situation in general and special practice would have been even more difficult than it has become in recent months. Having examined sources of supply so thoroughly, the Medical Personnel (Priority) Committee might now profitably revert to the scrutiny of Service establishments in order to ensure that the economies they exercised a year ago are being maintained. The profession is indebted to this Committee, consisting mainly of medical men who have devoted much time and thought to the problems of man-power, and very specially to Dr. G. C. Anderson, without whose constant attendance as Secretary of the Central Medical War Committee the Committee might often have been at a loss for accurate information.

THE PRESENT POSITION OF HYPNOSIS

Hypnosis has had a chequered history. At first it was viewed with suspicion, partly because of its mysterious nature, partly because of the dubious personality of one at least of its pioneers. However, in the hands of Bernheim in France, and in this country of practitioners like Bramwell, it became a highly respectable and fairly popular method of treatment. It is surprising to read in Bramwell's book that hypnosis was used with apparent success in such conditions as phobias, which are nowadays supposed to depend on complexes of a kind which pure suggestion seems ill qualified to reach and to modify. Fluctuations of this sort in the popularity of a method of treatment are not unfamiliar in medicine as a whole. They have usually characterized a remedy which depended for its effect entirely on suggestion, this effect having something unsatisfactory about it, particularly as regards its permanence. There are other reasons why such remedies fade into the background and disappear. Suggestion in any form to be successful depends above all else on the therapist himself, and the efficacy of the method is proportionate to the vehemence of his own belief in it. It is more difficult for the modern doctor to have a profound belief in hypnosis than it was for his predecessor. With the progress of science hypnosis has come to look less and less respectable, and more and more like a sort of confidence trick.

---

[1] *British Medical Journal Supplement*, 1941, 1, 44.

It is also possible that, immured and even protected behind his test-tubes, the physician's own personality has become less and less a permanent feature in treatment, and has become incapable of operating in any powerfully suggestive fashion.

The use of hypnosis has been handicapped also by the fact that it has been imperfectly understood. A great deal of what passes for hypnosis is not hypnosis at all; some patients are merely drowsy, some have actually fallen into a true sleep on the hypnotist's couch, and others, to please the doctor, have politely agreed that they were hypnotized. Hypnosis, properly so called, is unmistakable. Its outstanding characteristics are the patient's apparent abandonment of jurisdiction over his own will and his complete passivity. The scope of consciousness appears also to be restricted, allowing hallucinatory developments to occur that are independent of the environment. How often such a state of extreme passivity, suggestibility, and limitation of consciousness figures in a session in which hypnosis has been claimed has never been submitted to statistical examination. There have been other disadvantages in the method besides uncertainty as to the nature of hypnosis and its dependence on the hypnotist's own belief in his technique. At one time, in the French courts, post-hypnotic suggestion was urged as a defence in cases of crime. People under the influence of hypnotic suggestion, it was supposed, might do anything. Then a famous experiment recorded by Janet seemed to " debunk " this claim for ever. Recently, however, a hypnotized subject was induced to throw acid into the face of another person, who was, however, in reality protected by a screen of invisible glass. The vehicle of this experiment showed all the signs of horror and repugnance as he threw the scarifying fluid. The dramatic capacity of the hypnotized subject and the likelihood that his total appreciation, conscious and unconscious, of the situation was as great as that of the operator's, makes even this modern experiment difficult to accept at its face value.

For all these reasons it is good that an attempt should have been made to investigate what is essentially a psychological process by what is the most refined method of clinical investigation of mental states that exists. Ferenczi emphasized that in hypnosis and suggestion the patient transferred to the hypnotist his infantile loves and hates. Sandor Lorand[1] recently had an opportunity of analysing a young woman who had been hypnotized by someone else, and his observations in this case seem to confirm Ferenczi's view. It became clear that the patient had been much attached to the physician, and that she had entertained unconsciously a desire for seduction. Lorand points out that the hypnotic treatment was mishandled and might have been used to satisfactory effect. The fundamental basis of the relationship, however, of subject to operator under hypnosis, according to this psycho-analytic investigation, is the reactivation of feelings for the parents, dating of course from early childhood.

The subject is of some importance to-day in view of the findings of the last war—more than in this one so far—that painful experiences of an adult sort may be repressed and give rise to symptoms, the latter disappearing when the memory is recovered under the influence of hypnosis. It is more than a little doubtful whether hypnosis in this sense has much in common with the sort analysed by Lorand. Certainly the therapeutic aim is much more limited, and whether the subject's attitude to the operator involves a reactivation of early wishes in such circumstances is a matter requiring elucidation. It happens that so far this war does not seem to have produced the same crop of amnesias from psychological trauma as the last. Moreover, there has appeared in the method of injection of an intravenous barbiturate a means of recovering such memories with more certainty and in a shorter time than by ordinary hypnosis. At the same time there is a temptation to rush to the barbiturate method when hypnosis could quite well succeed. It may be, however, that there is something to be said for the view that it is a better therapy which does not involve the extreme emotional dependence that hypnosis, even for this limited purpose, probably does. In this connexion we may recall Freud's remarks in *An Autobiographical Study*: " Increasing experience had also given rise to two grave doubts in my mind as to the use of hypnotism even as a means of catharsis . . . even the most brilliant results were liable to be suddenly wiped away if any personal relation with the patient became disturbed . . . ; the personal emotional relation between doctor and patient was, after all, stronger than the whole cathartic process, and it was precisely that factor which escaped every effort at control." Treatment by means of injection is more readily accepted and understood by the modern patient than hypnosis is likely to be. It has been used also with some success as an adjunct to some analytic types of psychological treatment, and even in psychotic syndromes, in which hypnosis is usually ineffective.

The correct practice seems to consist in a judicious choice of psychological methods of treatment, including hypnosis. Increasing knowledge need not destroy all belief in the usefulness of the latter, but should rather refine its application and strengthen reliance on it in its proper scope of application. Lorand's two cases are an example of its discreet employment in the light of knowledge not available to the pioneers.

SEASONAL INFLUENCES

Dr. A. B. Fitt, who holds the chair of education at Auckland University College, has for many years been interested in the problem of seasonal variations in bodily and mental processes. He has made many observations himself as well as a comprehensive study of the literature, and his conclusions are presented in an excellent monograph.[1] An impressive body of evidence points clearly to a fundamental rhythm. During the autumn–winter period, say, September–January in the northern hemisphere, weight increase is at a maximum and height increase at a minimum, this being reversed during the spring–summer period. The most important observations on mental growth and function are those of Prof. Fitt himself. He finds a higher level during the autumn–winter period, the climax occurring about mid-winter. Thereafter there is a rapid fall in the early spring, followed by a recovery about April and May; the level then attained, however, is not as high as during the winter. It is also noted that muscular capacity, as measured by the dynamometer, is maximal during spring–summer, as also are such indexes of instability as suicide or the onset of mental illness.

An even more interesting series of observations deals with differences associated with period of conception. There can hardly be any doubt as to the reality of this variation. Those conceived during the period autumn–winter are on the average slightly taller, heavier, stronger in hand-grip, and more intelligent than their fellows, as well as less likely to die during the first month of neonatal life. Once again the maximum occurs towards the end of the favourable period and the minimum early in the spring–summer period. A rough estimate of the order of magnitude of the greatest differences when adult life is attained would be half an inch in height and one and a half points of I.Q. Prof. Fitt will make orthodox biologists shudder by calling this an effect on "inheritance" and by his light-hearted assumption that it is determined by the total organic condition of both parents at the time of the conception of the child, and is therefore due presumably to something passed on to the fertilized ovum via the gametes. It is much more probable that the differences are related to the state of the mother during pregnancy. In view of the correspondences found it seems likely, however, that the important period is the earliest part of pregnancy. After reviewing various lines of evidence Prof. Fitt rejects hypotheses which seek to relate these differences directly to external factors. To give one reason alone, the periodicity is too universal and too constant to be explained in terms of temperature or diet. He puts forward the suggestion of an endocrine rhythm to which the pituitary makes the most important contribution. This rhythm is doubtless affected, however, by external factors, of which solar light is likely to be the most important. Interesting comparisons are made between some human observations and those on hibernating animals. The general picture is of an autumn-winter period of minor stress with weight increase at its maximum, as is also mental activity and emotional stability. This is succeeded by the period of major stress. Increase in height is now maximal, and the generally unfavourable character of the period is reflected by slight, though real, differences in many indices. It seems likely, furthermore, that the most unfavourable period of all is the pale reflection in the human subject of that critical phase when the hibernating animal is adjusting itself once more after its comfortable winter sleep to the strain and perils of an active life.

VITAMIN B_1 DEFICIENCY AND THE NERVOUS SYSTEM

One of the difficulties of applying experimental results to clinical medicine is the great variation in response shown by the various types of animal to the same procedure. This apparent lack of uniformity is often attributed to individual and species differences. In pigeons, for example, vitamin B_1 deficiency produces head retraction, which rarely if ever occurs in the human subject. A recent series of papers by Swank and his colleagues[1 2 3] from the Harvard school goes far to elucidate some of the problems of symptomatology of B_1 deficiency in pigeons, with special reference to pathogenesis and morbid histology. Several points of clinical interest are brought out in this study. There appears to be little doubt that both clinical and histological aberrations from normality vary according to the speed at which the deficiency is brought about, which in turn is largely dependent on the ratio between B_1 intake and caloric value of the diet. With very acute onset there was increased tendency to the appearance of opisthotonos, whereas when the effects of B_1 deficiency were minimized by a lessened carbohydrate intake ataxia and leg weakness preceded the head retraction, which often did not occur. This is of importance in the use of opisthotonos in pigeons for assay purposes, indicating the necessity for maintaining a standard caloric intake before conclusions are drawn as to the amount of vitamin B_1 ingested. It is obvious that the different clinical syndromes are primarily the result of different rates of development of the deficiency. Therapeutic experiments also throw light on the pathological processes at work. Opisthotonos yields rapidly to the administration of vitamin B_1, indicating that the symptom is the result of metabolic upset which has not yet caused structural damage. Leg weakness, on the other hand, requires days or even weeks before B_1 therapy produces recovery, suggesting that there is some tissue degeneration. These speculations are confirmed by the authors' studies of the histological changes. With opisthotonos there is generally no structural change in the nerve fibres of either the central or peripheral nervous system, whereas with leg weakness there is degeneration of the peripheral nerve fibres, the number involved being roughly proportional to the severity of the clinical condition. A further connexion between the clinical picture and histology is seen in the finding that clinical improvement is closely correlated with the regeneration of myelinated nerve fibres. Degeneration begins first in the axis cylinder at the distal end of the fibre, and with long-continued B_1 deficiency progresses centrally, followed by changes in the myelin sheath. The cell body very soon shows signs of chromatolysis, which persists even during recovery of the neurone, suggesting that the changes in the cell are manifestations of the neurone's effort to regenerate its axis cylinder. Furthermore, it is obvious that even with complete withdrawal of the vitamin sufficient B_1 is released from the tissues to stimulate, or at least enable, the neurone to make attempts at regeneration. Indeed, with complete starvation the vitamin B_1 derived from the tissues is sufficient to reduce considerably metabolic abnormalities and structural changes in nerve tissue. It would be interesting to know whether there is any correlation between the dosage of vitamin B_1 and the rate of histological regeneration and clinical improvement, or whether above a certain not very high optimum no further benefit is obtained.

The experimental results recorded in these papers throw considerable light on the different clinical pictures of B_1 hypovitaminosis. There is little doubt that the rate at which B_1 deficiency is produced is an important factor in this connexion. Unless there is complete inanition the intake of aneurin by man rarely reaches such low levels as can be obtained experimentally, so that the common syndrome approximates that of the chronic type of deficiency. There is still left for exploration the part played by factors other than speed in the pathogenesis of such conditions as Wernicke's encephalopathy, which Campbell and Ritchie Russell[4] suggest is largely the result of defective supply of vitamin B_1.

PREMARITAL EXAMINATION LAWS IN THE U.S.A.

Thirty States in the U.S.A. have adopted some form of compulsory medical examination before the issue of a marriage licence. The requirements vary in the different States. Seventeen require examination only for syphilis, and the remainder include in their demands freedom from other communicable venereal diseases. North Carolina and Rhode Island demand absence of tuberculosis, and, in North Carolina and Oregon, epilepsy, mental defectiveness, drug addiction, and chronic alcoholism are regarded as being deterrents to marriage. The method by which these examinations are made is different: some States permit any licensed physician to perform them, and others demand that they be carried out in the State in which the marriage licence is issued. The lack of reciprocity in the different

States naturally leads to difficulties, more especially at a time when America's young male population is being scattered over the country. It is necessary for a male applicant to arrive sufficiently far in advance of the wedding ceremony to allow the performance of the required laboratory tests. A haemolysed specimen, a clerical error, an unexpected positive, or some other unanticipated obstacle may have embarrassing consequences. But in certain cases, and more especially in the case of a pregnancy, a licence may be issued even although the requirements have not been fulfilled.

In commenting on the action of the laws dealing with premarital examinations, Drs. G. F. Forster and H. J. Shaughnessy[1] point out that the lack of reciprocity is because they have originated in different States and have been formed by the forces of opposition and support existing there. The differences would have been eliminated had there been some central authority to co-ordinate them. But, whilst the fact that each State has been responsible for its own legislation has brought certain disadvantages, it has also brought advantages. Errors which were made in the early experiments have been avoided in some of the later ones, and in time it should be possible to establish some form of reciprocity which will make for smoother running and impose less hardship on those who are applying for a licence. This American experience should be of value to this country if it should ever decide to make the issue of a marriage licence depend upon medical evidence of a clean bill of health for the contracting parties. Were we living in Erewhon a certificate of psychological fitness would also be a stipulation.

TUBERCULOSIS IN OLD PEOPLE

Widely divergent views on prognosis in tuberculosis of old people have been expressed as the result of clinical studies alone (Brooks and Lander,[2] Snell,[3] Rest[4]). A. Arnstein[5] throws light on the pathological aspect of the condition. His study is based on 135 necropsies of people over 60 at a large hospital in Vienna between 1929 and 1934. "Anthracosis" of the mediastinal and bronchial lymph glands is known to be common in elderly people who have lived all their life in the atmosphere of industrial districts, but it is believed to be of no practical importance. Arnstein shows that, though no causal connexion with dusty trades can be found in these people, the changes in the glands are often anthraco-silicotic or silico-tuberculous. In his cases the lungs themselves were free from gross silicotic changes; the degree of pneumoconiosis in the glands corresponded with that found in the earliest stage of industrial silicosis, when the root glands are mainly affected. The very low dust content of the air breathed by the ordinary inhabitant even of a smoky district would account for the length of time necessary for the development of even slight silicotic changes and for their appearance only at an advanced age. Fibrous periglandular adhesions between the glands and neighbouring structures may occur in the course of the pneumoconiotic inflammation, but more often they have already been present as a sequel to old tuberculous foci. Such foci often contain viable tubercle bacilli, and the superadded "silicosis" may apparently cause reactivation of the lesions either because silica has a definite attraction for calcium (Amor[6]), thus causing decalcification of the foci, or, as demonstrated by Arnstein, because phagocytes densely packed with carbon particles may cause destruction of hyaline and even cartilaginous tissue. The reactivated tuberculous lesions will in favourable cases soon heal again, but in others caseation spreads along the mediastinal lymph glands to reach the venous angle, where bacilli may enter the blood and thus cause haematogenous lesions; or the morbid process may invade and damage neighbouring structures. The latter results may occur with glands that are pneumoconic only. Indeed, the author stresses that the differential diagnosis between pneumoconio-tuberculosis and pneumoconiosis, as well as between the former and simple tuberculosis of the lymph glands, is often very difficult, even on histological examination. Among Arnstein's cases, in 51 instances lymph glands erupted into the bronchial tree. The perforation was followed by chronic pneumonia in 2 cases, by lung abscess or gangrene in 5, by caseating lobar or lobular pneumonia in 24, and by no lung damage in 20 cases. In 34 cases diverticula of the oesophagus were produced, 13 of which ruptured into the bronchial tree. Perineuritic fibrosis may cause nerve paralysis: the left recurrent laryngeal nerve was found damaged in 47 cases, the right recurrent in 2, both these nerves in 4, other branches of the vagus in 7, the right phrenic in 4, and the left in 6 cases. Rupture into a blood vessel caused a fatal haemorrhage in 15 patients.

Analysis of Arnstein's material shows an increasing incidence of gland lesions with advancing age, and a marked preponderance in women. An explanation offered for the latter fact is that more women than men with healed tuberculosis reach old age. Arnstein points out that the conclusions drawn from his observations might not apply in full to other places, but here he has at all events found good examples of the conditions in the Students' Museum of U.C.H. Medical School and in the Wellcome Museum, and he has already seen 2 or 3 cases in hospital. He reports fully one case from the Northern Hospital, Winchmore Hill, of a woman of 55 who died from caseous tuberculous pneumonia caused by eruption of a tuberculous mediastinal gland into a bronchus. This instructive communication should lead to the study of a sufficiently large post-mortem material on similar lines here.

TREATMENT OF MALARIA IN BRITAIN

The occurrence of cases of malaria among Service personnel in this country has prompted the Ministry of Health and the Department of Health for Scotland to invite the co-operation of retired medical officers of the Colonial and Fighting Services in the diagnosis and treatment of such cases. Many civilian hospitals and practitioners suddenly faced with what is, in this country, a rare disease may be glad to accept the help of someone who has had practical experience of the disease in the Tropics. It is anticipated that only very infrequently would such help be called for, but on these occasions it might be urgently needed. The Ministry of Health and the Department of Health for Scotland would be grateful if any officer who can offer his services in this connexion would forward his name and home address to the Director of Establishments, Ministry of Health, Caxton House, Tothill Street, S.W.1.

Sir Henry H. Dale, M.D., P.R.S., who was recently appointed a member of the Governing Body of the Lister Institute of Preventive Medicine, has been elected by the Board as its Chairman.

ECONOMY OF MEDICAL MAN-POWER

THE SHAKESPEARE COMMITTEE'S REPORTS

The Ministry of Health publishes to-day through H.M. Stationery Office the first and second interim reports of the Medical Personnel (Priority) Committee, commonly known as the Shakespeare Committee, and these are reproduced below substantially in full. The membership of the Committee has been as follows:

Sir Geoffrey Shakespeare, Bt., M.P. (chairman), Sir Girling Ball, Major-General R. J. Blackham, M.D., Dr. J. Crighton Bramwell, Dr. J. A. Brown, Dr. W. M. Knox, Sir Hugh Lett, Bt., Surgeon Vice-Admiral Sir Percival Nicholls, Prof. R. M. F. Picken, M.B., Major-General R. C. Priest, M.D., Air Marshal Sir Victor Richardson, M.B., Prof. Sydney Smith, M.D., Mr. H. S. Souttar, Sir Alfred Webb-Johnson, and Sir Charles Wilson, P.R.C.P. Dr. G. C. Anderson attends the committee as Secretary of the Central Medical War Committee. Sir Hugh Lett was a member in virtue of his office as President of the Royal College of Surgeons; his place was taken by his successor in the Presidency, Sir Alfred Webb-Johnson, in July, 1941, and the vacancy thus created was filled by the appointment of Sir Girling Ball. Major-General Blackham replaced Major-General Priest in October, 1941.

The Committee's terms of reference were: "To investigate in the light of the recommendations made in January, 1941, by the Committee of Inquiry on Medical Personnel [the Robinson Committee] what further steps can usefully be taken to secure the utmost economy in the employment of medical personnel in H.M. Forces, the Civil Defence Services, the Emergency Hospital Scheme, and all other medical services, including general practice; and having regard to any recommendations made as a result of such investigation to report from time to time what should be the allocation between the above-mentioned services of the available medical personnel."

The first interim report, addressed to the Minister of Health, is dated August 6, 1941, and the second interim report February 11, 1942.

FIRST INTERIM REPORT

We have now held 25 sittings since July 3, 1941, and members have acquainted themselves by personal visits to selected establishments with the general arrangements designed to meet Service and civilian medical needs of the population in those areas. We intend at a later stage to present to you further reports. In view, however, of the demands made by the Services for the next six months, we wish to make a number of urgent recommendations, the need for which we have already established.

We have investigated the demands of the three Services for medical personnel to satisfy their requirements for the six months ending on December 31, 1940. Since the "Robinson Report" each Service has reviewed its establishments and requirements and effected economies. Considerable economies have been secured during the progress of our inquiry, and the view of the fighting Services is that their demands have been reduced to a minimum if the efficiency of medical services is to be maintained and further expansion programmes are to be met.

We have further inquired into civil establishments making any appreciable call on medical man-power, particularly the E.M.S. and other hospital and health services. We are not in a position at present to express an opinion on many of the medical personnel requirements of these services.

With the information at present available to us we are of the opinion that the withdrawal of the proposed further number of medical practitioners from civil practice will impose a severe drain on existing resources. In view of the shortage of doctors it is imperative to review continuously their distribution, so that further economies can be effected. Some of these can only be secured by the closest co-operation between the Services mutually with one another and between them and the civil authorities. We have already received much evidence of co-operation between the Services, both between the Directors-General in London and between senior medical officers of the three Services throughout the country. Nevertheless, the degree varies from Region to Region, and much more might be accomplished if the good will already existing expressed itself through a recognized machinery. In few areas has a concerted effort been made to ensure the most economical use of the available medical man-power, whether Service or civilian.

In the Civil Defence Regions the health and hospital services are already co-ordinated under the direction of the senior administrative officers and regional medical and hospital officers of the Ministry of Health. Army and R.A.F. Commands are based respectively on geographical and functional considerations. We are therefore of the opinion that the Civil Defence Regional areas provide the best basis for reviewing the requirements of those types of medical services which can be regarded as more or less static.

Recommendations

We therefore recommend that a committee should be set up in each Region composed of senior medical officers representing the various commands of the fighting Services in that Region and the regional medical and hospital officers of the Ministry of Health and such other officers as may be necessary. The liaison medical officer for the area, appointed by the Central Medical War Committee, should also be a member of the committee. The chairman should be a neutral person, preferably the Regional Commissioner or his deputy. This committee should meet regularly and should be charged with the duty of ensuring the maximum co-operation to meet civil and Service needs in the area. It should be directed to make a review immediately and should make further reviews from time to time in order to effect economies in medical man-power within the Region and the elimination of under-employment and overlapping of medical personnel.

The reports of the Regional Committees should be sent to the Minister of Health and the Secretary of State for Scotland, and copies should be sent by them to the Departments concerned and to the Medical Personnel (Priority) Committee, to enable that committee after receiving the comments of the Departments to make appropriate recommendations. If agreement can be reached within the Regions effect should immediately be given to the agreed proposals with the consent of the Departments concerned, and such agreements should be recorded in the reports.

In the view of your committee this review and the action taken on it should lead to an economy in medical personnel.

In the meantime we recommend that the Minister of Health and the Secretary of State for Scotland request the Central Medical War Committee to continue to provide medical officers to the Services at the present rate. At a later stage we shall be able to assess more precisely the number required. To facilitate the work of the C.M.W.C. in obtaining the necessary numbers, part of which will have to come from hospital staffs, the Ministry of Health and the Department of Health for Scotland should be asked to obtain complete particulars as to the bed accommodation and staffing of all civilian hospitals in Great Britain.

In certain areas it will be extremely difficult, on the basis of the present age group, for compulsory recruitment to obtain for the Services all those male practitioners who can be spared from the civil medical services of the area. This is due to the uneven geographical distribution of the age groups throughout the country and to a relative shortage in certain areas of male practitioners under 41. In addition, there is a large number of practitioners of military age engaged in the hospital services whose removal would be impracticable.

We have considered as a solution the possibility of the exercise of compulsory powers to transfer general practitioners into areas where there is more urgent need of their services. There are difficulties which could be overcome in transferring a practitioner from one salaried post to another, but there are insuperable difficulties involved in transferring practitioners from one practice to another on account of the personal nature of the services rendered and the difficult financial problems involved. We therefore suggest that the Ministry of Labour should consider the advisability of raising the age limit for liability for service for the medical profession by five years over that for the remainder of the population.

The satisfaction of the Service requirements must be made in part by further depleting existing hospital staffs. To enable this drain on the staffs to be met with the minimum loss of efficiency it is essential to have power to move the medical staff employed on a whole-time basis (in A, B2, and B1 posts) from one hospital to another with greater freedom than at present exists. For this purpose we recommend that the present powers of compulsion under Defence (General) Regulation 58A should be used by the Minister of Labour, through the appropriate National Service officers, so as to secure that such medical personnel in whole-time employment can be transferred as desired to meet not only the threat of invasion but any other period of stress. Greater mobility will ensure economy in personnel.

Finally, we recommend that the Medical Departments of the Army and Air Force should take immediate steps to see how far economies can be effected by pooling their medical officers of the A.A. Commands and Balloon Barrage and employing them on an area basis.

SECOND INTERIM REPORT

Since our first meeting on July 3, 1941, we have held 49 sessions, and have carefully considered the whole problem of the medical needs of the country in relation to the civilian population and the fighting Services. We have inquired into the distribution of medical personnel between the fighting Services, civilian practice, the public health services, and hospitals throughout the country. We have further examined the demands made by the three fighting Services and the Indian Medical Service, and have considered the provision of medical personnel to meet all the needs of the civilian population. We have investigated existing sources of supply for the Services and, where they have proved inadequate, have made recommendations to supplement them. We have heard evidence given by medical representatives from the armed Forces and civilian services, and a number of witnesses whom the committee considered would be of assistance in their deliberations.

Since submitting our First Interim Report we have periodically framed our recommendations in the form of resolutions on which action had been taken by yourself, by the Secretary of State for Scotland, and by your Departments. A summary of these resolutions is attached in the Appendix.

We deem it advisable to summarize as briefly as possible the conclusions we have reached on problems connected with the supply and distribution of available medical personnel to meet all requirements. The Central Medical War Committee carried out on Jan. 24, 1942, a count by age groups of practitioners on the *Medical Register*, showing the distribution of these practitioners and the numbers recruited to the Services.

Requirements and Economies

When we commenced work in July, 1941, we first investigated the requirements of the fighting Services for the last six months of the year and examined the demands submitted by them to the Central Medical War Committee for this period. In August each Service was requested to review its establishments and requirements and to submit a revised estimate, taking into consideration the economies effected as a result of recommendations put to them by us. These revised estimates were discussed with the Service representatives, and agreement was reached upon minimum requirements after considerable economies had been effected. The C.M.W.C supplied in the three months July, August, and September to the Services a number of medical men which in October left a deficit to meet the needs of the three fighting Services for the last three months of the year of 1941.

We examined in detail reports of members of the committee who visited certain Service establishments and discussed this with the Service Departments. We also impressed upon these Departments the serious shortage of medical practitioners and the importance of adequate medical supervision for the civilian population. The Services appreciated the position. They again reconsidered their requirements and effected further economies. The R.A.F. accepted cuts amounting to about 37% on its original demands for the last six months of the year; the Army so revised their estimates that they reduced their original demands to nearly 40%; while the Navy accepted a cut of 50% on their requirements for the last three months of the year. We carefully considered these revised requirements and made recommendations regarding the number of doctors to be supplied for the last three months of 1941 to each of the fighting Services. Practically all of this number were supplied to the Services by the C.M.W.C. by the end of the year 1941; the deficit was made up in January, 1942.

Considerable economies have been effected in medical personnel by the three Services. As a result of co-operation between the War Office and the Air Ministry, which we recommended in our First Interim Report with a view to securing the pooling of medical officer services in the A.A. and Balloon Commands, there has been substantial economy in the Balloon Command. We feel, however, that still further effort should be made in this direction

Indian Medical Services

We have heard evidence from representatives of the India Office regarding the supply of doctors for the I M S., and we asked the Central Medical War Committee to make every endeavour to supply a specified number of medical officers a month to meet the demands of this Service. Although it appeared that compulsory powers could not be exerted to compel doctors in this country to accept service in the I M S., we were informed that the Government of India had introduced certain liberal concessions regarding antedate, etc., for candidates in India, and it was hoped that the application of these concessions to candidates in this country would result in a satisfactory supply to meet India's needs. We realized, however, that if volunteers for the I.M S. were not forthcoming it would be necessary to make up deficiencies in the supply of European doctors for the Army in India by the dispatch of an additional number of R.A M.C. officers.

We were informed that difficulties had arisen in regard to the service of R.A M C officers with formations of the Army in India because of the reduction of such officers, when serving outside India, to British rates of pay. We were of opinion that this policy stood in the way of the appointment of R.A.M C officers to posts normally filled by I M S officers, but we understand that the policy has now been changed and that the War Office and India Office have reached agreement on the conditions under which the Army in India may draw to a larger extent than before on the R.A.M.C. for its supply of medical officers.

Emergency Medical Service

We have given consideration to the organization of the E.M.S. This service was designed primarily for ensuring prompt medical treatment for civilian air-raid casualties, but it was intended that it should be available also for the treatment of Service casualties, and also for ordinary sick civilians transferred from central institutions to safe areas. Its functions have since been extended to the treatment of evacuees, and to other categories of patients. Its main duty during quiet times has been the treatment of Service sick, Service accidents, and the ordinary civilian sick patients.

The primary function for which the service was set up still determined the nature of its organization, but we consider that the extent and basic principles of this organization should now be reviewed. The instructions issued to the Minister of Health and the Secretary of State for Scotland were to set up an organization capable of dealing with casualties resulting from intensive air raids on a large number of populous districts simultaneously. Efficient units (hospitals, first-aid posts, etc) had, therefore, to be set up throughout the country, and only to a limited extent was any attempt made to render the organization mobile. Mobile teams were formed, but little use was made of them. The difficulties of making a new appreciation to deal with so many unknown factors are obvious, and in the meantime you and the Secretary of State for Scotland have accepted our recommendation of a percentage cut on hospital staffs. We understand that these cuts are now being applied and relate to medical staffs enrolled in the E.M S as well as to those directly employed by the hospital authorities.

It should be possible, without running unjustifiable risks, to reduce many of the establishments, and even to close a number down altogether. In our First Interim Report we expressed the opinion that, to enable hospital staffs to be reduced with the minimum loss of efficiency, it was essential to have power to move those of the staffs employed on a whole-time basis (in A, B2, and B1 posts) from one hospital to another with greater freedom than at present exists, thus ensuring economy in personnel. There is also a considerable number of civilian mobile teams, but it appears from the evidence submitted to us that very few of these have in fact been used. Not only ought the whole-time staffs of all hospitals, civilian and Service, to be more mobile, but every endeavour should be made to secure the greatest degree of co-operation and interchangeability between the medical units of the civilian and the fighting Services.

For all these reasons we recommend the preparation of schemes within each Region embodying these principles of co-operation and mobility. We understand that your Department is working out a scheme to achieve this purpose.

Ambulance Trains

We have examined the organization for the evacuation of casualties by ambulance trains under the E.M S. scheme. We are of the opinion that the use of whole-time medical practitioners for civilian ambulance trains in this connexion, even when these practitioners are unsuitable for service with the Forces, is an uneconomic use of medical man-power, and is not justifiable. Part-time medical officers carrying out other duties near the points at which trains are normally located should be used for this purpose.

Requirements of the Three Services and the I.M.S for First Quarter of 1942

We have considered and given our approval to figures showing the present estimated requirements of the three fighting Services and the I.M.S. and have forwarded to you our opinion on the numbers which should be supplied during the first quarter of 1942. These requirements imply a monthly rate of recruitment in excess of that which the C.M.W.C. can hope to arrange from the normal sources of supply. To meet these requirements we have submitted certain resolutions, which are set out in the Appendix. The substance of these is as follows: (1) A percentage reduction in the whole-time medical staffs of civilian hospitals other than mental hospitals (2) A reduction of 100 in the medical staffs of mental hospitals. (3) A restriction for the time being to six months of the period of office of all holders of "A" posts in hospitals.

In the first of these resolutions we recommend that whole-time medical establishments of civilian hospitals should be reduced by a percentage cut. In the course of our investigations we had formed the impression that here there was scope for considerable economy in medical man-power. In view of the absence of statistical data upon which to base definite conclusions, we recommended, in our First Interim Report, that statistical returns of the medical establishments should be required from all civilian hospitals and medical institutions. These returns were duly obtained, and were placed at the disposal of our secretaries for tabulation.

Examination of many of the individual returns, and of statistical tables prepared from them, led us to form the opinion that: (1) Reduction of medical staffs is feasible in all types of hospitals. (2) London hospitals are more generously staffed in all categories than provincial hospitals. (3) A proportionately more drastic reduction is possible in the staffing of mental hospitals. These findings led us to consider various possible methods for effecting reductions in hospital staffs. Our ultimate conclusions were embodied in the resolutions, already referred to, which you and the Secretary of State for Scotland accepted and upon which action is being taken by the Departments.

Consideration of Other Sources of Supply

We have considered other sources of supply which we were advised might yield additional medical personnel for the Services, for example:

We carefully examined the possibility of employing alien doctors in hospitals and as assistants in general practice. We have satisfied ourselves that the majority of employable alien practitioners have already been absorbed into various appointments, and that it is unlikely that this source will assist further in our problem to any material extent. We have had before us figures showing the number of alien practitioners employed and unemployed.

The possibility of obtaining doctors from the United States of America and the Dominions was carefully explored. Surgeon Rear-Admiral Gordon-Taylor informed us that on a recent visit to the United States and to Canada he had discussed with the authorities concerned the possibility of a further supply for Britain of doctors from these countries. He thought that no further doctors would be forthcoming under the American Red Cross Scheme. He informed us that Canada might possibly make some further contributions. A number of doctors from the Royal Canadian Army Medical Corps have been seconded to the R.A.M.C., but we consider that no further practitioners are available from the Dominions, who have already heavy commitments for their own armed Forces as regards medical personnel.

The question of raising the age of conscription for the medical profession by five years above the normal age of recruitment of other sections of the population was examined. This has now been partly met by the recent National Service (No. 2) Act of Dec. 8, 1941, but some time must elapse before it will produce an effective supply. We hope that as a result of the proclamation all medical practitioners between 41 and 51 will be registered in one group at the earliest possible date. We regard the proclamation as an urgent matter. Our Chairman has written to you, and to the Minister of Labour and National Service, on this subject, and has also emphasized the importance of women doctors within the age group of 20-30 being made subject to the same compulsory procedure that now applies to male practitioners.

The Public Health Services and the School Medical Service have been scrutinized. We are of the opinion that there is a source of supply in these services, and have submitted to you and the Secretary of State for Scotland a separate resolution on this subject. (See Appendix.)

Other problems were brought to our notice, from the examination of which it was considered that further economies might be effected, increased use made of available medical man-power, or sources of supply augmented, e.g.:

(*a*) More transport for medical officers in charge of troops of all Services throughout the country would enable one medical officer to carry out more work than he can at present. We wish to call the attention of the Secretary of State for War to this recommendation so that an adequate number of cars may be made available for medical officers.

(*b*) The number of medical boards required by the Services for the examination and categorization of recruits was studied with a view to considering a reduction in their number and the saving of the time of a number of medical officers. We concluded that any contribution in the way of economy in medical personnel from this source would be negligible.

(*c*) We have also had before us a suggestion that certain E.M.S. hospitals might with advantage be transferred to the Army Medical authorities. It does not appear to us that any material economy of medical man-power will result from this proposal, but we are assured by the Medical Director-General of the Army that the transfer will not, in itself, lead to any increased demand for Army medical officers, and it appears that it will be of real value to the Services in providing improved training facilities and opportunities for clinical experience. Accordingly so far as the matter lies within our province we would like to commend the project.

General Conclusion

Our investigations have satisfied us that the Services are now fully alive to the limited resources available to meet their needs and those of the civilian population, and to the consequent necessity for the utmost economy in medical man-power. As a result of their co operation with us the call by the fighting Services on the resources of medical personnel during 1941 was substantially reduced. We hope that our recommendations for the saving of medical man-power in civilian hospitals, and the deliberations of the Regional Committees will help to solve our problem during the next six months. We are, however, convinced that continued vigilance in the economical use of medical man-power is necessary.

We are now examining the demands of the Services for the last nine months of 1942, and we hope to submit at a later date a separate report based on these demands and on the conclusions of the Regional Committees, and to make recommendations after receiving the comments of the various Departments concerned.

Appendix: Summary of Resolutions

Nov. 19, 1941.—(1) That the Minister of Health and Secretary of State for Scotland be advised to instruct the Central Medical War Committee to revert for the present to its original plan of calling up for military service A men in hospitals at the termination of their first six-months tenure of such posts and to call up forthwith the present male holders of the extended A posts subject to one month's notice being given to the hospitals. (2) That the Minister and the Secretary of State be advised to instruct the Board of Control and the General Board of Control for Scotland respectively that mental hospitals and institutions for the mentally deficient should reduce the existing strength of their staffs so as to provide by Jan. 21, 1942, 100 men of military age fit for service in the Forces. The names of the men to be released to be submitted to the Ministry of Health and Department of Health for Scotland for transmission to the C.M.W.C.

Dec. 3, 1941.—That the Minister of Health and the Secretary of State for Scotland be advised: (*a*) To instruct the Central Medical War Committee and the Scottish Medical War Committee to revise, in consultation with bodies responsible for hospital services, the medical establishments of civilian hospitals (other than mental hospitals) with a view to reducing the numbers of medical officers holding A, B2, and B1 posts, the aim being to reduce the all-over strength on Aug. 1, 1941, of whole-time medical officers in hospital by 10% in the Provinces and 15% in London (including Sectors), provided that the reduction in teaching hospitals should not exceed half the above percentages in the immediate future. (*b*) That the C.M.W.C. and the S.M.W.C. should be instructed to consider expediting as far as possible the placing of newly qualified medical men and women in hospital posts. (*c*) To instruct the C.M.W.C. and the S.M.W.C. to examine closely the number of young medical men engaged in pathological appointments and in research work with a view to the release of as many as possible for either special or general medical duty with the fighting Forces.

Jan. 7, 1942.—That the Minister of Health and the Secretary of State for Scotland be asked to consider further methods by which local authorities by closer co-operation or otherwise can release from their Public Health Services more medical officers of both sexes of military age for service with one of the armed Forces of the Crown.

MEDICAL SCHOOLS AFTER THREE YEARS OF WAR

ARRANGEMENTS FOR THE NEW SESSION

For the fourth year the winter session of the medical schools opens under war conditions, but arrangements are now better stabilized than they could possibly have been in the earlier period, and while many inconveniences attaching to dispersal remain, it can be said that the volume of teaching has not been lessened nor its standards lowered. The examination results have been good, but it is obvious that the number and perhaps the quality of the pre-medical students will be increasingly affected as the best boys leave their public schools and join up with one or other of the fighting Services. Some London medical schools are beginning to experience a small diminution in the numbers seeking admission for the commencement of medical studies, others declare the numbers to be stationary, and one school in the Provinces speaks of being inundated with applications for next session, particularly from women. The number applying there is said to be far in excess of the quota allowed.

So far as the pre-clinical subjects are concerned, several of the London schools, after three years' experience in the Provinces, are returning to London. In October King's College Medical Faculty will come back to its old buildings in the Strand, and pre-clinical subjects will be taken there for the students not only of King's College Hospital but of Charing

Cross, St. George's, and Westminster. Middlesex, too, has decided that its pre-clinical students shall return to London from Leeds, where they have been accommodated for two years. The pre-clinical schools of the London Hospital and of St. Bartholomew's are to remain at Cambridge. St. Thomas's pre-clinical and pre-medical studies are still centred at Godalming, where laboratories and class-rooms have been constructed, and the generous co-operation of the headmaster and governing body of Charterhouse School is available. The first-year students of St. Mary's continue to be the guests of Berkhamsted School, and those of the London School of Medicine for Women remain at Exeter for the present.

The London Schools

The final-year students of St. Thomas's have just left their quarters at Guildford and have returned to the hospital in London, where an increased number of beds have been opened and out-patient teaching has been restored almost to pre-war standard. A sufficient part of the school library has also been moved back to London. Outside London, at Godalming, a full department of pathology has been installed in a specially leased house. The main medical school library has been accommodated at Hydestile, where lecture rooms and full students' amenities have also been provided. Following their preliminary six months, the clinical students spend two periods, each of six months, attached to medical and surgical firms at Hydestile, and these are followed by six months' midwifery, gynaecology, and paediatrics. The facilities for teaching midwifery are considerably better than in several of the pre-war years in London.

St. George's Hospital Medical School has also returned to the metropolis. Since May last the students have done the whole of their work at the hospital at Hyde Park Corner, with the exception of midwifery, which continues to be taken, through the courtesy of the Middlesex County Council, at the West Middlesex Hospital. During the past year the number of in-patients and out-patients at St. George's has steadily increased and clinical material has been abundant. Should less happy conditions recur, the hospital has re-equipped its convalescent branch at Wimbledon on modern lines, and the medical school has rented and equipped a large country house immediately adjacent to serve for emergency purposes. But unless dispersal again becomes necessary, it is intended that the school shall remain at Hyde Park Corner, with the country establishment as an annexe.

The clinical school of Charing Cross is still evacuated from London, at Boxmoor in Hertfordshire. The whole of the first clinical year's work is done at Ashridge Hospital (1,200 beds). During the second clinical year clerkships and dresserships are served in all the special departments, and for this work the facilities of the parent hospital at Charing Cross, as well as those of Ashridge, Stanmore, Edgware (midwifery), and others, are utilized. In the second and third clinical years students are posted by rota to Charing Cross and Ashridge for residence as emergency dressers. As a wartime modification the removal to Boxmoor has worked well, and residence at Chaulden House for sixty students has provided the advantages of a corporate life, but the difficulties, especially the consumption of time by the staff in having to travel out of London to teach, will not grow less, and the extended use of the school in London for the instruction of senior students is being considered.

St. Mary's is fortunate in that both school and hospital buildings remain undamaged. Nevertheless, some dispersal of students is maintained. Students in their clinical years continue to hold posts in four other sector hospitals in addition to St. Mary's, but it is at St. Mary's that the whole of the second M.B. course and the latter part of the clinical teaching is now taken. Consequently the student has at one time the opportunity of seeing a wealth and variety of clinical material in the sector and at another of participating in organized student life at the parent hospital. The large number of resident posts made available by the E.M.S. in the sector continue to provide house appointments for all students on qualification. One feature of the past year has been the large attendance—an average of 130—at the meetings of the Medical Society.

The medical school of the London Hospital, apart from its pre-clinical school at Cambridge, is now organized at three centres: the London Hospital Annexe and Warley Woods Hospital at Brentwood (542 beds), Chase Farm Hospital at Enfield (925 beds), and the London Hospital itself in Whitechapel (416 beds), together with neighbouring London County Council hospitals comprising 2,500 beds. Students starting clinical work are sent to Brentwood for the first twelve months, where they have an introductory course in medicine and surgery and carry out six months' clerking and six months' dressing. They are then sent to Enfield for a three-months course in pathology and similar courses in neurology and orthopaedic surgery, after which they are posted either to the London Hospital, the maternity unit in Hitchin, or other associated hospitals for practical experience in obstetrics. Finally they come to the London Hospital as senior students for further clerking and dressing in the wards and work in the out-patient departments. Lectures are given at Brentwood in applied physiology, elementary medicine, surgery, and pathology for junior students; at Enfield in pathology, morbid anatomy, bacteriology, biochemistry, midwifery, and gynaecology; and at the London Hospital the final systematic lectures in surgery, medicine, public health, medical jurisprudence, and therapeutics for senior students.

No Change

Most of the other London schools have no changes to report so far as the instruction of clinical students is concerned, and the arrangements set out in the article in the *British Medical Journal* of Sept. 6, 1941 (p. 345), remain unaltered. This is true of Westminster, King's College, University College, and the London (Royal Free Hospital) School of Medicine for Women. Middlesex Hospital has not found it necessary to make any major alteration in the distribution of students during the clinical years. The increasing need to supply the fighting Services with the younger qualified men has not simplified the task of the school in arranging the teaching in the sector hospitals, but the standard of teaching has been maintained, thanks very largely to the co-operation of the Middlesex and Buckinghamshire County Councils and the Board of Governors of Mount Vernon Hospital. The association with the Royal Hospital, Wolverhampton, which began in 1940 has also developed most satisfactorily. At Guy's and St. Bartholomew's there are no striking changes to report. The clinical students of St. Bartholomew's are distributed at Bart's itself, Friern Emergency Hospital, Hill End Hospital, and Cell Barnes Hospital. The main improvement during the year has been the establishment of a first-class pre-clinical medical course under the professors of medicine, surgery, and pathology at Hill End Hospital; also the introduction of a new tutorial class in pathology at the same hospital for final-year students.

Postgraduate teaching in London at the British Postgraduate Medical School, Shepherd's Bush, is continued on pre-war lines, with bedside tuition and lectures rather than specific courses, though special courses on war medicine and surgery and other subjects have been held in alternate weeks. A number of undergraduate students have been accepted at the request of the deans of their respective schools, and a limited number of refugee graduates have been accepted to enable them to put in the necessary hospital practice to take British qualifications. In addition the obstetrics department is providing facilities to enable a limited number of undergraduates to comply with the University of London's requirements in obstetrics and gynaecology.

Provincial and Scottish Schools

In the provincial schools there have been still fewer changes. At the University of Manchester various small curriculum alterations have taken place. With a view to facilitating earlier qualification and of affording wider hospital experience, senior students have been employed as temporary officers under direction at local hospitals. The Board of the Faculty of Medicine has recently passed a resolution whereby students during the war period, having completed all appointments, may apply to sit for Part II of the Final M.B., Ch.B. examination (qualifying) after thirty months' clinical work. At Leeds, again, the Board has decided to accept the recommendation of the Ministry of Health and to shorten the clinical period of study from 36 to 30 months, as a temporary emergency measure. Steps are being taken to introduce the shortened course next month. Students who would normally take their degree in

March, 1944, will be able to take their final examination in September, 1943.

One innovation at Sheffield is of interest. All students entering the university next session must undergo a thorough clinical examination, for which the university pays. Heretofore such an examination on entry has been offered on a voluntary basis, but the response has been poor. In the case of medical and dental students the physical investigation will include *x*-ray examination of the student's chest and a Mantoux test. A further *x*-ray examination is made before beginning clinical work, and again two years later.

At Bristol, instead of candidates taking the second M.B., Ch.B. examination in anatomy, physiology, elementary pathology, and elementary pharmacology six terms after completing the first examination, they will sit for anatomy and physiology after five terms of professional study—that is, in March—and will take the examination in elementary pathology and elementary pharmacology one term later—that is, in June. The whole examination must, as hitherto, be passed before students may begin hospital practice. In Birmingham no changes are contemplated for the new session. In Cardiff the raid damage to the Royal Infirmary has been considerably repaired and about 220 patients can now be taken in. The medical and surgical units, with rather more than 100 beds, still remain at the Whitchurch Emergency Hospital, and the convalescent home is still maintained as a full service hospital. The travelling of students has been well arranged, and the time-table of attendances has been altered so as not to interfere with tuition. The clinical school at the Welsh National School of Medicine has its full number of students, and the applications for admission to pre-clinical studies pursued at University College, Cardiff, are very large, so that selection has to be made. Altogether the medical students in Cardiff number about 350. The new Pathology Institute is proving of great value in teaching. Clinical pathology is made a feature of sixth-year study.

In the Scottish universities certain important changes in the curriculum have been made at Aberdeen and at Edinburgh. At Aberdeen, to enable students to graduate within five years, a fourth term is being held during the summer vacation for students who finished their fourth year in June, 1942. At Edinburgh the subject of psychiatry has been introduced into the final professional examination. The examination, consisting of a two-hours written paper and an oral, will be held at the end of the spring term—that is, in March—of the fourth year of the medical curriculum. At Glasgow, on the whole, it has been possible to continue medical teaching on normal lines. Patients in teaching hospitals are somewhat fewer, so that teaching facilities have to be slightly reduced, but it has not been necessary to discontinue any special courses. The main hospitals are undamaged and the routine of the students is not substantially altered. At present there are 1,070 students in the medical school, of whom about one-fifth are women.

The increased emphasis on the aspects of preventive social and industrial medicine and the shortening of the time devoted to the clinical period are creating some difficulties for the schools, but so many difficulties have been overcome during these last three years that the outside observer has come to believe—even if those concerned in the administration do not quite believe it themselves—that the schools are equal to all trials and emergencies.

Changes made in the organization of the British Hospitals Association, states the report of council for 1941, include a strengthening of area committees, alteration where necessary of area boundaries, and the setting up of a new area organization for South Wales. They are preliminary to a reconstitution of the council and amendment of the articles of association consequent on the decision to admit convalescent homes, sanatoria, and mental hospitals to membership. During the year an advisory committee on nursing matters was formed; also a subcommittee on hospital and contributory scheme income limits. Other items to which the association gave time and thought during a busy year were the salaries of hospital staff other than nurses; hospital staffing problems created by the demands of the Services and the Ministry of Labour; the supply of deep *x*-ray apparatus; the teaching hospitals committee set up by the Ministry of Health; and last, but by no means least, soap rationing as it affects hospitals.

Correspondence

Lister Technique for Emergency Surgery

SIR,—Under certain circumstances as a result of enemy action surgical operations may be required to be done under adverse conditions. The advanced highly skilled surgical technique in strict aseptic surroundings with an abundance of sterilized equipment (dressings, instruments, water, etc.) may have no place where war conditions have temporarily abolished such amenities.

The practical application of the Lister technique is probably unknown to the majority of the younger generation of surgeons, for they have never carried it out. There is some ridiculous idea extant that if any antiseptic—e.g., carbolic acid—should "soil" a wound, either by mops, surgical instruments, etc., tissue *necrosis* and wound *infection must* follow. Like so many surgeons of my generation I have successfully done a large number of major surgical operations in cottages, using the kitchen table for the operation, with towels around the wound area wrung out in carbolic solution 1 in 40, instruments out of the same solution, boiled mops out of normal saline or 1 in 10,000 hydrarg. perchlor. solution, with a paraffin lamp for the illuminant.

As improvisation may at any time be required I would plead for an immediate revival of the Listerian technique. This could be done by practical demonstrations at operations in surgical centres, also by carrying out the technique at all hospitals, including the E.M.S. ones. Further, in these days of rubber-glove shortage, surgical operations may have to be done with bare hands. Operations were done in the pre-glove era with equal success when compared with the present-day glove epoch. It may be that some surgeons and nurses will require to relearn the art of getting their hands surgically clean. The use of gloves, so long as they remain unperforated, excuses shortcomings in inadequate scrubbing up.—I am, etc.,

Newcastle-upon-Tyne. R. J. WILLAN, F.R.C.S.

Pernicious Anaemia

SIR,—I was glad to read the plea of Prof. L. J. Witts (Aug. 22, p. 227) for better supervision of patients with pernicious anaemia. But I would disagree with him when he attributes so much of the blame to the patients themselves for neglecting treatment when they feel themselves cured. In my opinion the unsatisfactory state of affairs which exists at present is largely due to ignorance on the part of some practitioners of the elementary principles of treatment of pernicious anaemia. They frequently reduce maintenance treatment to grossly insufficient amounts, and, indeed, sometimes tell their patients that it is unnecessary so long as they feel well. It is clear that the danger of the development of subacute combined degeneration is insufficiently appreciated.

Because of this experience I have made it a practice to explain carefully to patients before they are discharged from hospital or the out-patient clinic the necessity for continuing treatment for the rest of their lives, and I believe that very few patients will neglect treatment if they understand the position clearly. I feel convinced that the death rate from pernicious anaemia would show a sharp fall if all practitioners realized the importance of maintenance treatment in sufficient amounts. Because this treatment should be controlled by periodic blood examinations special clinics are obviously desirable, and I welcome the attention which Prof. Witts has drawn to this aspect of medical planning.—I am, etc.,

Aberdeen HAROLD W. FULLERTON.

Anaemia in X-ray Workers

SIR,—The Hospital Officer Memorandum No. 3/25 recently circulated by the E.M.S. to Class 1A and 1B hospitals (*Journal*, Aug. 1, p. 137) is, in my opinion, a dangerous document. The facts to which it refers are doubtless accurate, but the memorandum is apt to be misleading. Admittedly anaemia is not recognized as a specific effect of radiation, but it is wrong "in order to allay uneasiness and to afford guidance" to issue a memorandum which states this fact at some length and devotes only one-tenth of its space to a brief mention of the changes that do occur as a result of radiation.

The experience of the big London hospital *x*-ray departments with adequate space and protection and under close medical direction is certainly not an adequate guide to the possible experience of an E.M.S. hospital department unless the latter follows all the recommendations of the International Committee on *X*-ray Protection. The statement that "periodic blood examinations are advisable . . . as a reassurance to radiographers" is an inglorious understatement of what is considered necessary by radiologists with knowledge of radiographers who have had to leave *x*-ray work because of a white cell count which indicates damage by *x* rays. The final sentence that "the term '*x*-ray anaemia' has no particular meaning and should be avoided" is true, but again implies that there is no danger from radiation.

The authors of the memorandum are to be congratulated on the skill with which it has been compiled. To doctors and lay officers without special knowledge and experience of radiation and its effects on the blood it is a convincing document which implies that the dangers of radiation to *x*-ray workers have been over-stated, and, in fact, are practically non-existent. To those with special knowledge it presents a series of statements which are probably incontrovertible, but the emphasis is false. The dangers of radiation, the signs of its effects (leucopenia, monocytosis, granulocytopenia), the danger to the skin and gonads, and the necessity for adequate protection should have been stressed, since otherwise the radiographer and those responsible for his or her health will follow even more readily the regrettable tendency to slacken rather than enhance precautions. *X*-ray anaemia probably does not occur but while blood cell changes do occur in the *x*-ray worker inadequately protected. A true document with a false emphasis such as this is dangerous, because, while it cannot be contradicted, it causes hospital boards and administrators to relax essential precautions.—I am, etc.,

F. Ellis,
Medical Director, Sheffield Radium Centre.

Hyperostosis Frontalis Interna

Sir,—Dr. C. T. Andrews's excellent and detailed report of a case of hyperostosis frontalis interna (Aug. 15, p. 185) prompts me to add two observations, one historical and the other clinical.

There is an interesting early reference to hyperostosis frontalis interna in an address on "Tic Douloureux" which was read at an evening meeting of the Royal College of Physicians of London 120 years ago by its president, Sir Henry Halford, and later included in his collected *Essays and Orations*. He relates, among others, the case of Dr. P., whose skull showed at necropsy "an unusual thickness of the os frontis, where it had been sawn through above the frontal sinuses, and at its juncture with the parietal bones. . . . Dr. P. had submitted with great patience to a division of several branches of the fifth pair of nerves, under the judicious operation of Sir Astley Cooper, who, on my mentioning to him the notion I entertained of the cause of tic douloureux, was so obliging as to show me the skull of a person who had died of this disease in the country. The internal surfaces of the frontal bone is a perfect rock-work." A third case, he notes, is of a lady who for 10 years had suffered "the tortures and the dreadful 'clawings and scratchings'" of a right tic douloureux. She had "an enormous thickening of the frontal, ethmoidal, and spenoidal bones in one part to the extent of half an inch; and the anterior lobes of the brain were curiously moulded and indented by the thickened bone. There was thickening also of the whole of the cranium, but not so great a degree anywhere as in the parts which have just been named."

It is curious that Sir Henry Halford should have met three cases of tic douloureux associated with a thickening of the skull whose description is consistent with hyperostosis frontalis interna. Though he conjectured that the osseous enlargement "injured directly, and at once, the affected nerves," he recognized that "there are other cases in which no such immediate cause of irritation can be discovered." The association must be rare. Six years ago I described 8 cases of hyperostosis frontalis interna before the Association of British Neurologists and I have since seen several others. None was associated with tic douloureux, though two had cranial nerve palsies. In one of these with a "jugular foramen syndrome" there was found after death a plaque of bone extending over and compressing the nerves passing through the foramen. Only 22 (approximately 1 in 10) of my cases of tic douloureux have had *x*-ray examination of the skull. None has shown significant hyperostosis.

Many cases of hyperostosis frontalis interna are symptomless and discovered accidentally. In patients complaining of chronic headache routine skull radiographs will sometimes reveal not only hyperostosis but occasionally other rare lesions—e.g., extensive calcification of the falx cerebri. In one of my cases a cerebral tumour was coexistent; its presence was suggested by a hemiparesis with papilloedema, and confirmed by ventriculography and subsequent operation.

Thus hyperostosis frontalis interna may give: (1) no symptoms; (2) chronic dull frontal ache; or (3) focal symptoms associated with local compression by bony bosses or plaques—namely, (*a*) the hypothalamic–pituitary group (adiposity, diabetes insipidus, sleep disorders, etc.); (*b*) progressive dementia; and (*c*) cranial nerve palsies. This suggests that the hypothalamic–pituitary disturbances are the *consequence* and not, as some have held, the *cause* of hyperostosis frontalis interna. Of its significant cause, or causes, we are quite ignorant.—I am, etc.,

Liverpool Henry Cohen.

Tuberculin Patch Test

Sir,—In your leading article (July 25, p. 101) you show how in differential diagnosis help can be obtained from a tuberculin test because a negative reaction *excludes* tuberculosis, hence its greater value in children than in adults. These points cannot be stressed enough. But tuberculous infection cannot be excluded unless the test is complete—i.e., unless it is ultimately carried out intradermally with O.T. or P.P.D. 1 in 100. In a large series of cases a higher tuberculin sensitivity may be found among those with active tuberculous lesions than among those with latent or healed lesions, but it cannot be assumed in the individual doubtful case that a test positive to a high dilution indicates active disease, or that a test negative to such a dilution excludes active disease. You recognize this, and advise that a negative patch test should be followed by a Mantoux test with 1 in 100 tuberculin. But you then state: ". . . . and when the practitioner can be satisfied that he has at his disposal a standardized uniform 'patch,' the test will probably prove of considerable value to anyone who is impelled by the exigencies of practice to sacrifice the greater accuracy of the Mantoux test to the convenience of the patch test." And again: "If the Mantoux test is not being as much used in general practice as it should be—and evidence points that way—the use of a properly standardized patch test will be preferable to no test at all." Are these statements compatible with the clear factual data given in the remainder of the leading article? You do not yourself seem quite happy about it, for you attempt to square your conscience by insisting on a "properly standardized" patch. But is not this asking for the impossible? We find it difficult to understand how "proper standardization" can be obtained of a test that involves several factors which may influence the dosage of tuberculin yet cannot accurately be controlled; for instance, degreasing, texture of skin, application of strip, etc.

There are two other points which should be mentioned. You quote several investigations in which the patch test is compared with the Mantoux test, and point to the fairly close similarity of results. But it is well to bear in mind that when such *ad hoc* investigation is done, greater care and supervision are probably exercised in the carrying out and reading of the patch test than might be the case when it is used in routine clinical practice. The second point is this. Your leader is apparently intended for general practitioners and physicians, but the tuberculin test is of paramount value in the follow-up of children as home-contacts in tuberculosis clinics. There many children are first seen before they are infected, and are then tuberculin tested periodically in order that the primary infection may be detected at its onset. It would clearly not be possible to dogmatize about the onset of a primary tuberculous infection unless the tuberculin test carried out a few weeks or months before had been complete.

The patch test is not used in epidemiological investigations from which reliable conclusions are sought. Apart from this, the test undoubtedly has, in certain circumstances, advantages of convenience, but it cannot be regarded as more than a preliminary step in tuberculin testing whatever advertising blurbs may state about it.—We are, etc.,

Donald Court.
Staines G. Gregory Kayne.

Ileostomy for Ulcerative Colitis

Sir,—It is not within my province to argue the pros and cons of this question, but it is possible that with the introduction of specific treatment the urgent need for this serious operation may no longer be necessary for ulcerative colitis. I am, however, quite convinced that if there is one form for which ileostomy is absolutely contraindicated that is amoebic dysentery. The statement that Mr. McNeill Love had undertaken it for that disease in 1917 may induce others to do so. We fortunately possess most potent specific remedies for amoebiasis, and experience in its treatment has led to the conviction that surgery of the intestinal tract is seldom, if ever, necessary. The impression I have formed is that the conditions which produced this emergency in Mesopotamia in 1917 were due to bacillary dysentery and not to the more chronic amoebic form, as there existed some confusion in differential diagnosis at that time.—I am, etc.,

London, W.1 Philip Manson-Bahr.

Medical Planning

Sir,—Dr. J. E. Gaze's letter (Aug. 15, p. 200) is interesting because it reveals an attitude which, in my experience, is not often found among the older members of the profession. I have been qualified for 10 years only, but during that time have done hospital appointments, "locums" in town, country, and prison, "put up a plate" in Suburbia, built up a practice, and joined the R.A.M.C. (T.A.) and been invalided out. I have also had the opportunity of observing my fellow men on the Harrow B.M.A. committee and on its subcommittee when we met the public health committee of the local council. Now, after prolonged treatment and convalescence and a period of manual work in the countryside, I am in the happy position of being able to look back from afar upon my professional contacts and experiences.

I have in the past longed for a medical plan, be it pure State medicine, health centres, or what you will, if only the result would mean: (*a*) an efficient treatment of the patient be he rich or poor, including, of course, prevention as well as cure; (*b*) an elimination of "business methods" in practice, even including the abolition of "goodwill," which seems wrong to me, perhaps because now I have little or no practice to sell; (*c*) an opportunity for every doctor to have a reasonable amount of leisure and holidays in order to keep himself mentally and physically fit, with a free period each year for postgraduate study, and access to a hospital; (*d*) the maintenance of the "family" doctor and of free choice for the patient; (*e*) a reasonable and ensured income; (*f*) suitable provision for illness and old age.

All of us upon qualification set forth with high ideals. Some accomplished the climb and have risen to well-deserved altitudes. Most of us, however, seeking in general practice an opportunity to preserve our independence, found that soon we were up against the hard facts of life. In practising medicine and at the same time earning a living we had to battle with the monetary-minded among patients and colleagues, sending out bills, recovering from a feeling of nausea at the jealousy, self-interest, and the "rackets" one sometimes met, paying rates to the local authority and thus helping to provide public health services which were cutting our own throats, and so on. There were many compensations, but it became increasingly evident that something was wrong with medicine somewhere.

If we have the courage openly to admit this let us all now seize the opportunity that these times offer to put matters right. Those with a practice which under present "goodwill" valuation is a lucrative one will expect compensation if things are altered, and perhaps a reasonable compensation will be paid—by whom and how, I will not even hazard a guess. If, however, none is forthcoming, let not those doctors break their hearts. There are many who have already given their lives. There will be more. There are many who are now prisoners of war, while the large majority of all those who have joined the Forces, whether as volunteers or conscripts, have suffered considerable financial loss. Those who now remain in civil practice and who are concerned in planning the future of medicine no doubt realize their responsibility is a great one. They would do well to consult their colleagues in the Forces, who will be busy, when demobilization comes, searching for the practices they left behind. And it will be the bounden duty of those who promised to look after them to help in rediscovering them.

The present muddle and overlapping in medicine can be ended, and need not necessarily be replaced by a bureaucratic nightmare of red tape, if only the members of the profession will maintain their dignity and cast aside the tendency to look upon the problem with more than one eye upon its financial aspect. The family doctor, with his intimate knowledge of the patient's home life, must be able to continue this psychological link with those he is called upon to treat. He must also be allowed to retain his individuality rather than be regimented and submerged by rules and regulations.

My considered opinion is that in our profession we shall never succeed in persuading the "stick-in-the muds" to move. I hope, however, that we can plan a State Medical Service which will contain all that is best in our present system. I trust that if pure State medicine comes, State education will accompany it.

The Medical Planning Commission has made an admirable start. It deserves our thanks and it is the duty of each one of us to give all the help and advice we can, for the problem concerns us all, whether we are old or young, specialists, family doctors, hospital officers, public health officials, or those who are now serving in the Forces. Their voice is well worth hearing, for they have had experience in civil practice, have sacrificed much, and are now experiencing some of the snags one would expect to find in a State Medical Service.—I am, etc.,

Bradworthy, Devon. C. G. Jones.

Sir,—Recently in your correspondence columns and at meetings here it has been urged that no major change in the conditions of medical practice should take place until the men now in the Services have returned to civilian life and have had an opportunity of expressing their opinions. This is a point of view with which we must all have the greatest sympathy, though, to judge by the almost complete lack of response to the numerous invitations sent to R.A.M.C. officers serving in this area to attend our discussions on medical planning, it would appear that even those still on home service are too fully occupied to be able to give consideration to these problems.

At a recent meeting here it was suggested that the profession should unitedly refuse to work any new scheme until the men in the Services can take part in its arrangement. Since it may be 3 years after the conclusion of hostilities before demobilization is completed, and since a further 3 years would have to elapse before the majority of the younger men could have had sufficient experience of civilian practice to be able to express an informed opinion, this seems to me to be an extreme point of view.

In support of this attitude it is often stated that "the last time" the position of men in the Forces was prejudiced by changes which took place during and immediately after the war in the conditions of practice generally. For the information of those who are too young to remember conditions at that time can anyone say what these changes were, and in what way they were prejudicial to the position of those who had been in the Services as compared with those who had remained in civilian practice? Of course one realizes that there must have been periods of individual unemployment after demobilization, but was this actually greater in medicine than in other professions?

It would seem that the answers to these questions would have some relevance when the optimum time for the inauguration of any new plan is under consideration.—I am, etc.,

Stirling W. Leslie Cuthbert.

Future Medical Service

SIR,—I have read a great many letters on the future of medicine and have frequently discussed it with other practitioners and lay men and women. The letter of Dr. Vallely (Aug. 8, p. 168) crystallizes a point of view held by many of our profession. It seems a competent, clear, and reasonable point of view, and yet I am sure it is quite wrong. It is just as wrong as the idea that State medicine in itself is the first step to the millennium.

When a number of intelligent people disagree on a fundamental issue, the reason is nearly always found to be a lack of definition of the problem. If the facts are not known or not clearly explained the field is left open for the theorist, the dogmatist, and the fanatic. For example, Dr. Vallely says "a whole-time salaried service would be wholly bad for the profession and the public," and "the lay press teems with evidence of the extravagance and inadequacy of State control." That is Dr. Vallely's theory, but here are some facts.

The Government distributes £75 million in unemployment benefits and allowances at a cost of £7½ million a year; £87 million in orphans' and old age pensions at £2½ million. On the other hand, the approved societies distribute £33 million in N.H.I. benefits at a cost of £6 million, while the insurance companies distribute burial, life, and sickness benefits amounting to £33½ million at a cost of £22 million, plus a shareholders' surplus of nearly £2 million a year. (I quote from the P E P broadsheet on Social Security, July 14, 1942—a magnificent compilation of facts.) In this connexion "the extravagance and inadequacy of State control" is not obvious, to say the least.

Yet I agree about the "stultifying" and "soul-destroying" effect of Governmental bureaucracy, and this leads to the next argument which is in urgent need of clarification. Those who argue against State medicine make the point that the concomitant bureaucracy will be a "tyranny," "an evil thing," "a cause of frustration," and they assume that all bureaucracies must be bad. Surely that is untrue. The fact that a bureaucracy is necessary to administer any large concern is neither good nor bad in itself. It is merely a fact. But the *type* of bureaucracy can be good or bad. Many of the big business combines are run by most efficient bureaucracies: at times too efficient for my way of thinking. These one can call good, just as the bureaucracies of the Government are inefficient in many ways and can be called bad. So State medicine will be "stultifying" only if it is run by a bad bureaucracy. As the word "bureaucracy" is so prejudiced by use it will be wise to substitute "administration."

Now there is no need for bad administrations to continue. We must take what is good in the Ministry of Health and preserve its rule-of-thumb organization of statistics, routine, and so on, for it does that part well. But the art of medicine and the organization of practitioner and hospital services for the ever-changing needs of the community can and must only be run by active members of our own profession; and this must be one of the foundation stones of any State medical service. Our one aim must be to provide the best possible service, and we must eschew the evil which damns our Civil Service—the fact that promotion goes to those who make fewest mistakes (and consequently fewest decisions) and those showing initiative are frowned upon and penalized. It is imperative for our future welfare that we let no defeatist attitude stand in our way. We cannot accept the present administration of medicine as a good thing. We must decide exactly what we want and see that we get it. My experience is that if one knows what one wants and has faith and energy then that objective is attainable.

There is one more point to make. Dr. Vallely says that a whole-time salaried medical service is not inevitable. Does he realize that the Ministry of Health has a scheme to bring the dependants of the present insured persons under the N.H.I. Act, and that then 90% of the community will be on the panel? Surely that all but fixes the salaries of the majority of practitioners, and the N.H.I. scheme becomes an elaborate mechanism for excluding 10% of the community from what the supporters of an extended N.H.I. scheme consider the best possible service. If Dr. Vallely likes the idea of being a salaried practitioner under the present Ministry of Health, he has only to wait and nothing to worry about. But if not, it is an urgent necessity to agree upon a better scheme and stand up for it with all the power at our command. Agreement will only come with increased knowledge, and I know of no better starting point than the broadsheet from which I have quoted.—I am, etc.,

Leeds. R. A. MURRAY SCOTT.

Salaried Service and Competition

SIR,—Several writers recently have stressed the value of competition in keeping up a doctor's keenness for his work. If success in this competition was determined primarily by clinical ability and conscientiousness such competition would be of great value to the cause of better medicine. Unfortunately, competition in general practice has degenerated into one for popularity primarily, and the doctor who attempts to educate and discipline his patients reaps a poorer harvest than the humbug and romanticist who liberally distributes placebos and habit-forming drugs.

In my view a salaried service on "public health" lines, which would eliminate the element of profit from sickness and encourage that most valuable kind of medical work, preventive medicine, would be a great and revolutionary step forward so far as general practice is concerned. I know that there are evils attendant on bureaucracy, but they are likely to be less serious, in my view, than those fostered by the present system.—I am, etc.,

Wallasey. LENNOX JOHNSTON.

Maternity Service of the Future

SIR,—It was good to read the letter of Dr. G. Winn Everett and her friends (Aug. 1, p. 143). We have in Scotland in essence the system there advocated. The general practitioner and midwife carry out as a minimum three ante-natal examinations; in the majority of cases they carry out the actual confinement and post-natal visits, the latter concluded by a very detailed examination of mother and child, a full report of which is submitted to the medical officer of health. We have the right, where our ante-natal examination justifies it, to obtain, without cost to the patient, expert obstetrical opinion, and also the right in emergency to obtain free expert obstetrical assistance. In certain cases, with the consent of the M.O.H., we can send our cases to hospital, and the cost to the patient depends upon her means. This latter is the only snag. Such cases should be admitted to hospital free of all cost to the patient. Detailed reports of all ante-natal examinations, of the confinement, and of our post-natal visits are also sent to the M.O.H.. To my mind our system is ideal for all concerned if each member of the team does his or her duty conscientiously, and two years' working under the scheme has been eminently satisfactory.

The essentials of obstetrics are not difficult to acquire, and were the feeding of our children and the housing, feeding, and working hours of our young adults in accordance with what is just and right and common sense, obstetrics would offer few emergencies beyond the capacity of the average conscientious general practitioner to tackle with success. Far too much is made by the "Munro Kerr school" and "official opinion" of our difficulties and of the success of the public ante-natal clinics and the large maternity hospitals. We have many women from these hospitals at the present time in this area. From what I have seen I would blush were they patients of mine.

To the women of this area our obstetrical specialist, Dr. Thomas N. Macgregor, has been an inestimable boon. Few as they are, obstetrical emergencies can be very terrible, and practising so far from a centre as we do, one feels very much alone, and such cases place upon our shoulders a strain that is almost unbearable. We had to manage in the old days, but now our specialist is a guide and a help whose assistance to our women is beyond words of description. We learn more in discussing our cases with him than we would from many postgraduate courses. I doubt if the latter are of any value.

Without obstetrics the life of the rural practitioner would not be worth while. Obstetrics binds us to the homes of our people, to our women, their children and grandchildren in a way that, in spite of our anxieties, makes life in the practice of medicine, of all lives, the finest to live. Our work is hard and financially of little attraction if that is the main aim of life, but otherwise, when we are near the end and look back we feel that we have justified the right to live; in spite of our failings we have won the affection and esteem of hundreds of our women, because, however poor the home, our care during pregnancy, at childbirth, and post-natally, and the bond created between us have made these "homes" in the truest sense of that word.—I am, etc.,

Tain
E. K. MACKENZIE.

SIR,—The letter of Drs. G. Winn Everett, E. A. Wilson, R. C. B. Ramsay, and S. A. Scorer (Aug. 1, p. 143) on maternity service of the future will meet with general approval because it promises greater security and better hospital accommodation for mothers. I would submit that there is one major fault in the present maternity services which is in no way corrected in the new proposals—namely, the relief of pain.

I am at present unable to obtain access to the literature, but I believe I am right in saying that of the 600,000 births occurring annually in this country more than 75% are attended wholely by midwives, and, consequently, the mother receives no form of anaesthesia. Of the cases attended by doctors, only the fortunate who can afford a specialist's fee get real relief; the remainder are grateful for a whiff of chloroform towards the end of the second stage. There are, I believe, two reasons for this: (1) inadequacy of fees, and (2) modern teaching in anaesthetics.

(1) An average fee for a working-class patient is in the region of 5 guineas. For this the general practitioner is expected to undertake ante-natal care, a day at least of worry and interruption of his normal work during the confinement, and post-natal visits. Yet the same family will willingly pay 15 guineas for the removal of tonsils and adenoids from their small son, an operation performed in half an hour and comparatively safe when compared with the lurking dangers of childbirth. (2) The young practitioner is imbued with a terror of chloroform, yet this is probably the only anaesthetic available to the general practitioner which is capable of giving adequate relief in labour.

In conclusion I would urge that the maternity service of the future should have as its ideal that every confinement should be attended by a doctor, adequate remuneration being assured by the State. Alternatively, the status of midwives should be improved to encourage more to enter the service, the training should be extended to include anaesthetics, and, finally, midwives should work in pairs, one acting as anaesthetist.—I am, etc.,

E. R. HARGREAVES,
Major, R.A.M.C.

Narco-analysis in Treatment of War Neuroses

SIR,—Having been working as a colleague of Dr. J. L. Clegg's for approximately the same length of time, I was interested in his objections to pentothal narco-analysis (Aug. 1, p. 140), and would like to mention one or two points which I have briefly discussed with him.

I would agree in the main that it is by no means a royal road to the unconscious, and must be regarded as a short cut, but I would still value it as such. It appears to me that different methods such as narco-analysis, and shock treatment too, may lay open different portals of the mind, or strike it at different levels; and, apart from the material so obtained, may have effects of which we are largely ignorant but which may nevertheless have curative value. In a recent case of anxiety hysteria I tried giving pentothal while the man was already under hypnosis, and the difference in reaction was striking: he immediately became more emotional, as though responding from a, one might say, subthalamic level.

In cases of massive amnesia, where hypnosis has failed, pentothal has given me results which would otherwise have taken many weeks. I have also found it of use in confirming one's impressions of the personality type; the character traits are shown up in an exaggerated light, particularly the inflated egoistic types, and the patient is the more convinced out of his own mouth. This is, of course, analogous to the verity induced by alcohol, the effect being more like that of large cocktails than the mellower one of a bottle of vintage burgundy.

Dr. Clegg should tell us, by the way, in what percentage of his 200 cases he used this method. Personally I have employed it in about 10%. The use of pentothal, like that of any other method, when we are dealing with subjectively toned material, and rapport is present, depends on the person using it as well as on the type of case. Dr. Clegg may get results with his methods which others may only get with prolonged analysis and others by the cruder mental enema of pentothal. There is also the question of permanence of effect.

So let us neither condemn nor appraise too highly a method which is still experimental as well as, apparently, therapeutic.—I am, etc.,

CHARLES BURNS,
Psychiatrist, E.M.S

"Silent" Sinusitis

SIR,—Dr. C. Newlyn Smith's inquiry (Aug. 22, p. 229) about the kind of contraction of the field in sinusitis will be best answered by reference to the field charts. Those for the second case have been reproduced in *Proc. roy Soc. Med.*, 1931, **24**, 891, and those for another case in *Trans. ophth. Soc.*, 1933, **53**. If Dr. Newlyn Smith has not easy access to these papers I shall be pleased to send him reprints.

Your other correspondent, Dr. J. J. Craig (p. 230), has answered the question, "Would not radiographs have shown it?" I have no desire to theorize; my one wish is to show that measures designed to drain the sinuses—one with operation, the other without—did promptly relieve the 2 patients, in both of whom every other measure had failed, in one for 7 years and in the other after a lifetime of headache.

I am glad to have Dr. Craig's confirmation of the existence of "silent" sinusitis. It is on the general practitioner that the continual care of these patients falls when specialists can give no help, so that I am glad he has found Proetz useful, though I have not had success with that method. To take the fields of vision by the perimeter, using a 1-mm. white object, takes 5 minutes. I am afraid I must differ from Dr. Craig, as this seems to me much more widely applicable than *x*-ray examination after the introduction of lipiodol, though this is also excellent for diagnosis. Very few chronic cases, in my experience, are without some involvement of the posterior sinuses, which is shown by the fields.—I am, etc.,

London, W.1.
ROSA FORD.

Single-handed Anaesthesia and Operation

SIR,—Recent correspondence in the *Journal*, concluding with Dr. A. H. Bartley's letter (Aug. 8, p. 170), has brought up a question which has occupied my mind ever since I started in general practice—i.e., should an anaesthetic and operation ever be attempted single-handed except in a gravely urgent emergency? My own opinion is that they should not, as if proper attention is given to the patient under the anaesthetic it is almost impossible to operate conscientiously, while the dangers of not watching the administration of the anaesthetic have been sufficiently emphasized in recent letters.

My own practice, however, differs in fact from my conviction; in midwifery particularly I often embark on the double responsibility. I have had no anaesthetic difficulties, as I make a point of inducing the patient to the depth required before handing over to the nurse, and then only permitting her to use a Mennell's inhaler, which will usually maintain the required depth with, I believe, complete safety. In an emergency I let the nurse induce with the Mennell's inhaler, which is usually sufficient to get a good second-stage anaesthesia. I have not been so fortunate with the operative procedure in these cases, however, and have, on one occasion at least, delivered an infant in the posterior position through inefficient anaesthesia.

My reason for attempting both responsibilities is simply that everybody does it, and I feel I hardly like to trouble my neighbours, except in cases which I know may prove difficult, when they do not trouble me; but I am sure the principle is wrong. Occasionally, for a very minor and quick procedure, I feel quite justified in giving a small dose of an intravenous barbiturate, for there the nurse can concentrate her whole attention on watching the patient's breathing. In variance to the usual opinion as to the safety of administration, I see no difference between a drug that has been injected and one that has been inhaled. While it is true that the inhaled drug is excreted with normal or, if necessary, artificial respiration, surely the injected drug is as rapidly destroyed in the liver, providing the blood is oxygenated—again by normal or artificial respiration. There is not, so far as I know, any danger with ordinary doses of any castastrophic damage such as may be produced by chloroform, which is the only drug likely to be used by a nurse-anaesthetist.—I am, etc.,

Birmingham W. BRIAN GOUGH.

Anaesthetic Convulsions

SIR,—A recent correspondent maintained that no mention of convulsions under anaesthesia is to be found in the earlier literature. Hewitt, on *Anaesthesia* (p. 367), says: "It is by no means uncommon for clonic muscular phenomena to arise during the second and third stages of chloroformization. . . . In some of the recorded cases of this kind, patients are reported to have had a fit or to have been attacked by epileptiform convulsions." In a footnote is added: "See Lord Lister's account of a chloroform fatality (*System of Surgery*, 3rd edition III, 615). In this case respiration ceased during an epileptiform spasm." "A similar condition has been observed under ether (*British Medical Journal*, 2nd May, 1885, page 887)."

I do not know how far back the records of the *B.M.J.* go, but it would be of great interest and, I think, of real value if this case could be looked up and republished.—I am, etc.,

JOHN ELAM.

⁂ The article referred to by Dr. Elam was written by Dr. Ernest H. Jacob, and was entitled "Deaths from Anaesthetics in 1884." They were briefly tabulated under the following headings: "Deaths under chloroform"; "Deaths from mixtures of chloroform and ether"; "Deaths from methylene"; "Deaths from ether." The one case in which there were presumably convulsions was that of a boy (age not given) operated on for "bronchocele." The following observation was made in the column headed "Remarks"; "Death by spasm expiratory muscles epileptic. (?) Lungs could not be inflated." At the end of his short article the author writes: "In reviewing the cases of deaths from chloroform and ether respectively, one is struck by the difference in the character of the operation; the deaths from chloroform being mostly in comparatively healthy persons, during slight operations. The deaths from ether occurred, without exception, in persons severely debilitated by disease."—ED., *B.M.J.*

Trilene and Cardiac Arrhythmia

SIR,—The letter of Drs. K. G. Lloyd-Williams and D. Hewspear (Aug. 8, p. 170) giving details of cardiac disturbances in a case of non-toxic goitre under trilene is most interesting. The writers incline to the view that the trilene was responsible for the trouble.

I have been using trichlorethylene for the past two years, during which time I have anaesthetized with this agent a considerable number of cases of thyroid, both toxic and non-toxic, without any untoward symptoms. I have not used chloral as a pre-operative sedative in these cases, and I note that the writers do not say whether they have used the chloral–trilene sequence before. The only trouble I have ever experienced with trilene is a very occasional tachypnoea of such degree that efficient tidal exchange is lacking and necessitates a change-over to some other agent.

Dr. Langton Hewer has not only pointed out the chemical resemblance between chloroform and trichlorethylene, each with three chlorine atoms, but he has also drawn attention to the dangers of primary cardiac failure following basal narcosis with trichlorethanol, which has three chlorine atoms in its structure as well. In view of the fact that chloral also contains three chlorine atoms, is it possible that the chloral–trilene combination had some deleterious effect on the heart which is not seen when these drugs are used separately?

A further point is whether the adrenaline, injected just before starting the trilene, had any bearing on the above. The effect of adrenaline upon chloroform narcosis is, of course, only too well known.—I am, etc.,

St. Leonards-on-Sea E. NEWTON PRICE.

A Light Trailer Ambulance

SIR,—I was interested to read Lieut.-Col. J. L. Moir's accoun of the "Duerr-Moir" ambulance (Aug. 8, p. 160). I should like to congratulate him on having exercised his mind to this extent in a matter of great importance.

For a considerable time we have recognized in Zone 3, Lancashire and Border District, that the standard type of stretcher, requiring as it does 2 to 4 men to transport 1 casualty a short distance, has a very limited function in open country, and that a light wheeled stretcher which can carry 2 casualties and be operated by 2 men is essential. We are developing here a purely hand-propelled "stretcher carrier" which is lighter and simpler than the trailer ambulance described; and—particularly as Lieut.-Col. Moir invites comment or criticism—I should like to state the main facts which I consider influence me in favour of this and against the trailer type.

1. The trailer ambulance can only operate on roads—that is, from casualty collecting points to the "rear area." On account of the additional weight and relatively complicated structure it would not be very easy to man-handle fully loaded over, say, 1 or 2 miles of rough country if necessary. One cannot presume that defended localities would always be within "hand carry" distance of C.C.P.s that are approachable by road, and a motor car is, of course, necessary in every case for the trailer ambulance. The trailer ambulance, therefore, chiefly caters for the relief of motor ambulances, and is concerned to a lesser extent with the difficult problem of transporting wounded from points of action to collecting points or beyond. Ambulance relief might largely be acquired by fitting simple box bodies to light car chassis. Where possible these could carry 4 or 6 cases. On the other hand, a light propelled "stretcher carrier" can operate where the trailer conveniently cannot, and could evacuate direct from defended localities "backwards" for a distance of a few miles if necessary, thereby relieving the motor ambulance to a certain extent as well as clearing the action area.

2. Increased shock to the casualties is a factor which must be considered during transport by trailer. It is impossible to avoid much bumping and side swinging when carrying a casualty in a light trailer of this type. Moreover, the protection from cold given by the light canvas sides and top is hardly offset by the hot-water bottles which would in any case be impossible to maintain.

3. Risk to the patients due to mechanical faults or breakdown—such as a broken towing attachment, tyre puncture, etc. —cannot be ruled out. Even with an attendant on the pillion seat (3 men on a light trailer would make it very unstable) the occupants of a trailer ambulance do not enjoy that degree of control which should be given to helpless men.

I mention these 3 points in fair criticism of an apparatus to which I have given some thought myself and which under favourable local conditions I consider might be of limited value. With restricted means of production, however, I believe that a light wheeled stretcher-carrier would be of greater potential value in so far as it would provide an answer to more of our problems. With this apparatus a motor car is not necessary; any 2 men can control it over a long distance; direct control of the casualties is simpler; and approach to and collection from the area of the casualties is possible. On the other hand, hilly country or roads form an obstacle which a motor-drawn ambulance could cope with better. In my opinion, however, the casualties in these should be placed inside a wooden or steel body and between the front and rear wheels.—I am, etc.,

K. VERNON BAILEY.

Vaginismus

SIR,—The interesting article by Dr. Joan Malleson (Aug. 22, p. 213) makes no mention of the rare but by no means mythical condition of deep or superior vaginismus which gives rise to penis captivus, the historical and bibliographical aspects of which I discussed some years ago (*Janus*, 1935, **39**, 196; and *Epitome*, April 11, 1936, para. 301). This "curiosity of medicine," which from ignorance or prudery on the part of the authors finds no mention in Gould and Pyle's classical work, is like the common form of vaginismus due to psychogenic spasmodic contraction of the levator ani. A typical but entirely fictitious case was reported by Osler in a mischievous mood writing under the pseudonym of "Egerton Y. Davis"

(Harvey Cushing: *Life of Sir William Osler,* 1925, **1,** 240). Although the state of the imprisoned couple has appeared so supremely ridiculous as even to raise a doubt as to its actual occurrence, the acute mental and physical suffering of the unfortunate victims during their conjunction and their feeling of shame after release has in one case at least (reported by Piltz, *Thèse de Paris,* 1931, No. 236) led to double suicide. In the few cases on record in which treatment is mentioned, chloroform has been given to the female partner to relax the vaginal spasm.—I am, etc.,

Kensington, W 8. J. D. ROLLESTON.

Self-medication and the Chemist's Shop

SIR,—The letter of Dr. Loewenthal was very much to the point, and, like him, I am surprised that such an important matter has received so little consideration from doctors generally. The fact is, however, that despite the "remarkable strides" and "wonderful discoveries" medicine is still a long way from being an exact science, and if people can obtain a "cure" in the chemist's shop they will continue to patronize it, as being a quicker and more economical method than visiting the doctor's surgery. One has only to look round any sick-room and see the litter of nostrums of all kinds to realize that for most of our patients the chemist is regarded as the first line of defence in connexion with illness. When taxed with this question the chemist's invariable answer is that if he was dependent on doctors' prescriptions for his livelihood he would have a very lean time indeed, and that force of circumstances has made him more of a shopkeeper than a pharmacist.

With regard to "counter prescribing," it is interesting to note that in most of these cases the "patient" comes along with a ready-made diagnosis, having previously consulted *Every Man His Own Doctor,* so that all the chemist has to do is to take out the appropriate remedy from its particular pigeon-hole and hand it over the counter. The transaction is rapid and easy; in many cases only a matter of seconds. Dr. Loewenthal appears to think that chemists might feel inclined to cut out this part of their business if the doctors gave an undertaking to stop dispensing; but would they? In most cases it is improbable that the increased revenue from prescriptions would compensate them for the loss in selling both their own and proprietary preparations, more especially in view of the enormous demand for the latter by a large section of the public. Moreover, if the customer cannot get his favourite remedy from the chemist he can easily get it elsewhere, as most of the small general shops stock patent medicines now. In addition the vested interests behind the proprietary drug trade are powerful, and as they are extensive advertisers in the lay press we could not expect much support from that quarter. There is a further complication in the fact that so many doctors' dispensers also fill the role of book-keeper and receptionist. It would be interesting to know what others think about the matter.—I am, etc.,

Leicester E. J. O'SULLIVAN.

Tietze's Disease

SIR,—Having read with interest the article on Tietze's disease by Drs. A. Morton Gill, R. Arden Jones, and L. Pollak (Aug. 8, p. 155) we thought the following case might prove of interest.

On July 27, 1942, a rating aged 19 reported at the sick bay on board H.M.S. —— complaining of pain and a lump in the chest. On examination a prominent swelling was seen just below and to the right of the xiphisternum. The swelling was "springy" and occupied the area of the seventh right rib cartilage, oval in shape, with its long axis, about one and a half inches, parallel with the cartilage with which it seemed to be continuous. It was not tender, but he complained of some pain on strenuous exercise. It was difficult to diagnose so we had an *x*-ray examination made. The report gave no structural abnormality. Potassium iodide as a form of treatment unfortunately produced acute iodism. In view of this and the lack of symptoms he was reassured and sent back to work. On examination 3 weeks later the swelling had diminished considerably but was still present. There were no symptoms.—We are, etc.,

W. F. VIRET.

Obituary

ARTHUR VERNON DAVIES, O.B.E., M.B., Ch.B.

We regret to announce the death at the age of 70 of Dr. Arthur Vernon Davies, O.B.E., Unionist Member of Parliament for the Rayton Division of Lancashire from 1924-31. Dr. Davies was a graduate of Victoria University, Manchester, where he qualified M.B., Ch.B. in 1895. He was subsequently house-surgeon at both the Royal Infirmary and the Northern Hospital for Women and Children, Manchester. During his 23 years in general practice in Shaw, Lancashire, Dr. Davies held many public appointments, including that of medical officer of health for Crompton. His lively interest in the health and welfare of his own town never lessened, and after his election to Parliament in 1924 he became one of the most regular attendants at the House of Commons. Any medical matters before Parliament were assured of his keenest interest. He was always a fearless critic of any measure with which he did not agree, and an equally staunch supporter of those of which he approved, especially those which he felt from his own experience would be of the greatest benefit to his constituents, among whom he had worked during his years in general practice. Ill-health compelled him to give up all his public work in 1931. Perhaps Dr. Davies's greatest professional interest was in the St. John Ambulance movement, which he joined soon after going to Shaw. As Assistant Commissioner for No. 4 District he put in a great deal of time during the last war, when he had under his supervision 20 auxiliary hospitals. After he retired to Surrey in 1922 he became for a time Commissioner for No. 8 District. In 1918 he was made a Knight of Grace of the Order of St. John of Jerusalem. Dr. Davies was a member of the British Medical Association from 1898 until his death, and a member of the Association's Parliamentary Subcommittee in 1930-1.

He leaves a widow, one son, and one daughter.

We regret to announce the death of Dr. MIDDLETON CONNON of Aberdeen, a well-known radiologist and an authority on the medical aspects of workmen's compensation. Dr. Connon, who was 67, qualified in 1896, and 2 years later took the D.P.H. After a period as resident surgeon and physician at the Royal Infirmary, Aberdeen, and the Royal Aberdeen Hospital for Sick Children, he practised with the late Dr. Key at Montrose, and then, in 1904, the year in which he took his M.D., he was appointed radiologist to the Royal Infirmary and lecturer in radiology to his old university. His association with the *x*-ray department of the Royal Infirmary continued for many years, and at the time of his death he was consulting radiologist to that institution. He served with the Forces in the last war, and afterwards was appointed examining officer for the Ministry of Pensions. He was also an examiner for the General Nursing Council in Scotland. Dr. Connon joined the B.M.A. at the time of his qualification, and for 11 years was honorary secretary of the Aberdeen Division, his period of office including the visit of the Association to Aberdeen for its Annual Meeting in 1939. Not a little of the success of that last pre-war meeting was due to his labours. At the same meeting he was vice-president of the Section of Radiology. He did much good work for the Association in the "Far North."

A well-known Edinburgh practitioner died on July 30 in Dr. JOHN MAY DARLING, D.S.O., consulting surgeon to the Edinburgh Eye, Ear, and Throat Infirmary. Dr. Darling, who was one of three brothers, all of whom were doctors, was the son of a Leith schoolmaster, and was born in 1878. He was educated at the Royal High School, from which he proceeded to the University of Edinburgh, where he qualified in 1903. He also studied for a time at the University of Marburg in Prussia. In 1906 he became a Fellow of the Royal College of Surgeons of Edinburgh. While house-surgeon at the Edinburgh Royal Infirmary he began to devote special attention to the study of the ear, nose, and throat, and after serving as clinical assistant in the otolaryngological department, he was appointed surgeon to the Edinburgh Eye, Ear, and Throat Infirmary, with which he remained associated for the rest of his life. During the last war he saw service in France, Belgium, Egypt, and Salonika, and retired with the rank of major R.A.M.C. He was medical officer to the Edinburgh Provincial Committee for the Training of Teachers at Moray House. He was a member of the Scottish Otological and Laryngological Society and the author of several papers in the *Edinburgh Medical Journal* on otological subjects. Dr. Darling had been a member of the British Medical Association for just over 30 years. He was a widower and is survived by two sons, one of whom is a medical man now serving in the R.A.M.C.

We regret to announce the death at Devizes on Aug. 4 after a long illness of Mr. James Thompson at the early age of 47. He was born at Penrith, Cumberland, in 1895 and received his early education there at Queen Elizabeth Grammar School. From Penrith he went to Edinburgh University, where he qualified M.B., Ch.B. in October, 1917. He served in France for the remainder of the last war, first as lieutenant and then as captain R.A.M.C. He was regimental medical officer to several battalions of the Bedfordshire Regiment, and it was while he was attached to them that he was awarded the M.C. After demobilization he took an assistantship at Taunton, where, in 1921, he married Miss Margaret Catherine Seaton. He then went back to Edinburgh University and in 1922 obtained his surgical fellowship. In the same year he acquired a practice in Devizes, where he lived until his death. He was the senior honorary surgeon to the District Hospital, Devizes, and consulting surgeon to the Wilts County Mental Hospital, Devizes; at one time he was consulting surgeon to the Wilts County Constabulary. He was also a borough magistrate. Mr. Thompson was a surgeon of outstanding ability and for some time had consulting rooms in Harley Street. Just before his illness began in January, 1942, he had been carrying out cancer research work along novel lines. He will be greatly missed by both professional and personal friends.

The Services

The Distinguished Service Cross has been awarded to Temp. Surg. Lieut. D. R. S. Howell, R.N.V.R., for bravery and enterprise in the successful operations which led to the surrender of the important base of Diego Suarez, and to Temp. Surg. Lieuts. J. W. Boland and R. Ransome-Wallis, R.N.V.R., for distinguished services in convoys to and from Murmansk, through the dangers of ice and heavy seas and in the face of relentless attacks by enemy U-boats, aircraft, and surface forces. Surg. Cmdr. W. F. Lascelles, Prob. Temp. Surg. Lieut. B. W. Davy, and Temp. Surg. Lieuts. J. B. Houghton, I. Miskelly, and J. W. J. Knowles, R.N.V.R., have been mentioned in dispatches for distinguished services in the Murmansk convoys.

CASUALTIES IN THE MEDICAL SERVICES

Col. William Walker, M.C., is included as "Died" in an Army Council Casualty List published on Aug. 21. He was born in 1890 and graduated M.B., Ch.B. at the University of Aberdeen in 1914, proceeding M.D. in 1932. In the war of 1914-18 he saw service in France and gained the Military Cross in 1918 for conduct described in the *London Gazette* as follows: "He proceeded to a village under heavy fire and succeeded in attending and evacuating several wounded. He only desisted when the enemy entered the village. Later, he succeeded in releasing a party of stretcher-bearers who had been cut off. Throughout the operations he has shown the utmost energy and courage." After the war he took a permanent commission in the R.A.M.C. and served in Palestine and India, in the Poona and Deccan Districts, and in 1931-2 he became deputy assistant director of pathology of the Northern Command, York. He contributed an article entitled "An Investigation into Cases of Cerebrospinal Fever in the Northern Command of the Army during 1931" to the *Journal of the Royal Army Medical Corps* in 1932-3, concluding with a plea for early diagnosis of the disease. From 1933 to 1939 he resided at North Shields, where he became assistant school medical officer to the County Borough of Tynemouth and honorary pathologist to Tynemouth Victoria Infirmary. On the outbreak of the present war he was recalled for service with the rank of lieut.-col., being promoted full col. soon afterwards. He had been a member of the B.M.A. for 24 years.

Acting Group Capt. Gerard Joseph Hanly, R.A.F., died in Aug. on active service in the Middle East. A native of Elphin, Co. Roscommon, he was educated at the University Colleges of Galway and Dublin, graduating M.B., B.Ch., B.A.O. of the National University of Ireland in 1923, also taking the F.R.C.S.Ed. in 1931. He entered the R.A.F. as flying officer in 1924, became flight lieut. in 1926, squadron leader in 1934, wing cmdr. in 1938, and was recently granted the acting rank of group capt. Before the war he saw service in India, Iraq, at Aden, and in Egypt. He leaves a widow. He had been a member of the B.M.A. since 1926.

Flight Lieut. Ian Gordon Lennox, R.A.F.V.R., died in Westminster Hospital on Aug. 8. He was born on Aug. 16, 1914, and was educated at the University of Glasgow, where he graduated M.B., Ch.B. in 1938. He held the post of resident medical officer at Paisley Infectious Diseases Hospital from May, 1940, until the following Sept., when he entered the R.A.F.V.R. as temp. flying officer, being promoted war subs. flight lieut. a year later. He was a brother of Mr. D. K. Lennox, F.R.C.S.Ed., of Blackpool.

Lieut. Donald Seymour Scott, R.A.M.C., is now presumed to have died of wounds received in May, 1940, while attending casualties at Cassel. He was born on June 27, 1911, the elder son of Mr. and Mrs. A. E. Scott of Maidstone, and was educated at Felsted School, at Emmanuel College, Cambridge, and at the London Hospital. He qualified M.R.C.S., L.R.C.P. in 1935 and took the degrees of M.B., B.Chir. two years later. He followed his 2nd Class Tripos (pathology) with a number of hospital appointments and obtained the M.R.C.P. in 1939. He entered the R.A.M.C. as temp. lieut. in Jan., 1940. He leaves a widow.

Prisoners of War.—Temp Major E. G. Collins, R.A.M.C., Capt A. W. V. Eley, R.A.M.C., Capt H. Houghton, R.A.M.C., Major W. R. Hunter, R.A.M.C., Capt. J. A. Learner, R.A.M.C., Temp Major J. R. A. Martin, R.A.M.C., War Subs. Capt. W. Milburn, R.A.M.C., War Subs. Capt. G. F. R. Parker, R.A.M.C., Capt. W. L. Petter, R.A.M.C., War Subs. Capt. T. St. J. H. Silvester, R.A.M.C.

Wounded.—Capt. L. G. Hannah, R.A.M.C., Capt. A. B. Waters, R.A.M.C.

DEATHS IN THE SERVICES

Col. Thomas Arthur Granger, C.M.G., I.M.S. (ret.), died at Exmouth on Aug. 4, aged 70. He was born on Aug. 12, 1871, and was educated at the University of Edinburgh, where he graduated M.B., C.M. in 1892. Entering the I.M.S. as surg lieut. in 1894, he became lieut.-col. after twenty years' service, col. in March, 1922, and retired four months later. He served in the Frontier expedition in Mekram in 1898 and in the North-West Frontier campaign of 1898-9, against the Chamkannis (medal and clasp). From 1911 to 1914 he was A.D.M.S., Army Headquarters, India, and from 1914 to 1919 was Honorary Surgeon to the Viceroy. He served in the war of 1914-18, and in 1915-16 he was A.D.M.S. at the headquarters of the Egyptian Expeditionary Force and the Mediterranean Expeditionary Force and from 1916 to 1918 was A.D.M.S., 4th Cavalry Division, in France. He was twice mentioned in dispatches and was appointed C.M.G. in 1918. He was the author of a small book on *The Art of Sailing*, 1933. He had been a member of the B.M.A. for 25 years.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* a rise in the notifications of whooping-cough, diphtheria, and acute pneumonia—172, 85, and 27, respectively, in excess of the previous recorded number—interrupted the general trend of a falling incidence of infectious diseases during the past few weeks. For the sixth consecutive week there was a sharp fall in the notifications of measles, the total being 636 fewer than in the preceding week. There were 31 fewer cases of dysentery, and the lowest weekly total for 12 months was recorded.

The rise in diphtheria notifications was due mainly to two counties—Lancashire and Durham, with increases of 34 and 35 cases. In the former county the chief centre of infection was Liverpool C.B. 42 cases, and in the latter it was Easington R.D. 23.

A small rise in the incidence of whooping-cough was fairly general throughout the country. In Yorks West Riding there was a total of 184 cases, compared with 127 in the preceding week.

In *Scotland* the incidence of diphtheria has increased for the fifth consecutive week. The chief centres of infection are Glasgow, Dundee, and Lanark, where 57, 25, and 13 cases were notified during the week.

Typhus

In *Eire* 5 cases of typhus were notified in the rural district of Kanturk, Co. Cork. This is the third outbreak during this year, the two previous ones being in Westport U.D., Co. Mayo, 5 cases, and Shillelagh R.D., Co. Wicklow, 3 cases.

Returns for the Week Ending August 22

The notifications of infectious diseases during the week in England and Wales included the following: scarlet fever 1,332, whooping-cough 1,235, diphtheria 629, measles 4,089, acute pneumonia 346, cerebrospinal fever 68, acute poliomyelitis 19, dysentery 59, paratyphoid 8, typhoid 15.

No. 32

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 15.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942 (a)	1942 (b)	1942 (c)	1942 (d)	1942 (e)	1941 (Corresponding Week) (a)	1941 (b)	1941 (c)	1941 (d)	1941 (e)

Medical News

The Medical Society of Pernambuco, Brazil, has recently celebrated the centenary of its existence.

The Trustees of the Leverhulme Research Fellowships have approved the award of a research grant to Dr. Frank Ellis, medical director of the Sheffield Radium Centre, for an investigation into the systematic effects of x and gamma radiation, their control and prevention. Application forms and information about Fellowships and grants may be obtained from the Secretary, Leverhulme Research Fellowships, Unilever House, Blackfriars, E.C.4.

The Board of Registration of Medical Auxiliaries has just issued a Register of Speech Therapists. Medical practitioners and hospitals and educational authorities may obtain free copies of the Register from the Secretary of the Board of Registration, B.M.A. House, Tavistock Square, London, W.C.1.

We have received from the Public Dental Service Association (15, Taviton Street, Gordon Square, W.C.1) a copy of the memorandum which the association has placed before the Interdepartmental Committee on Social Insurance and Allied Services (the Beveridge Committee). It presents the case for a national dental service as part of the health and medical services of the community, under the direction of a dental controlling authority. Preventive treatment, especially in pre-adult life, would be the chief aim of the service, and this be provided, for the present, through the existing private practitioner system.

The British Federation of Social Workers (5 Victoria Street, S.W.1) has issued in pamphlet form a report of the conference on social changes due to the war and their significance, held in London last February. Copies may be obtained from the honorary secretary, price 2s.

The Prime Minister of Australia announced on August 27 that he had co-opted Sir Earle Page to the Commonwealth War Council and that Sir Earle would attend the meetings of the War Cabinet, so that the knowledge and experience he gained as representative of Australia in the United Kingdom War Cabinet and on the Pacific War Council in London would be available to the Commonwealth Government.

The Association of Scientific Workers is organizing an exhibition to be held in November at the premises of the Royal Photographic Society, to illustrate the applications of photography to medicine, science, and industry with a view to making such information more widely available and better known to the public. Those who may be able to provide exhibits are asked to write to the Hon. Secretary, Photographic Exhibition Committee, Association of Scientific Workers, 73, High Holborn, W.C.1, for further details.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Ectodermal Dysplasia

Dr. W. A. H. BELL (Highgate) writes: Recently a case of old-standing almost complete alopecia has come under my care—a man of 40. He is the nervous, worrying type, and the skin of the body is dry and the finger- and toe-nails brittle and distorted. It would appear that there is some ectodermal disturbance affecting both hair and nails. At different times he has had all sorts of local applications to the scalp—ionization, etc.—without success. I should be interested to hear if any doctor has ever tried glandular therapy for these cases, and, if so, with what result.

Income Tax

Locumtenent and Assistant M.O.H.

"Z" did not work between January, 1941, and April 5, 1941; he acted as locumtenent for two weeks between the latter date and June 16, when he began work as an assistant M.O.H. on a salary plus weekly bonus, receiving a car allowance of 4d. per mile. He bought a Ford 8 on April 23, and sold it on June 20 at a loss of £44, buying a Standard 12 for £130.

*** "Z" is assessable for the current financial year on the basis of his earnings of the actual year. As the liability falls under Schedule E he can claim only such expenses as are incurred "wholly, exclusively, and necessarily in the performance of the duties of the office." The word "necessarily" is important—e.g., if "Z" uses a larger car than is necessary he cannot legally bring into the computation the whole of the resulting expenses. In point of fact it is the practice of the authorities to decline to make deductions from salary for any motor expenses when a mileage allowance is received, on the ground that taking one year with another the allowance may be presumed to cover the necessary costs. If, however, it can be shown that the allowance is in fact inadequate there is a legal claim to a deduction for such portion of the "necessary" expenses as are not covered by the mileage allowance. In making such a claim the cost of replacement basis for renewal of a car would probably be refused on the ground that it is not an annual expense, but the depreciation allowance—at, say, 24% of the written-down cost of the car—would be allowed in lieu of cost of replacement.

Cash Basis

E. desires to change the basis of his accounts for income tax as from March 31, 1941, treating his gross earnings as the amount of cash received in the year instead of the amount of the bookings less an allowance for bad and doubtful debts. The Panel cheque received on April 1, 1941, was £44 more than the amount received on April 1, 1942, and it is suggested that as tax has been paid upon the former amount the latter should be included in the cash basis account for 1941-2 instead.

*** In the first place we doubt whether the Revenue authorities will acquiesce in the proposed change in basis. The "cash receipt" basis has no legal validity and is accepted only when the gross earnings of a practice are reasonably stable and great difficulty is experienced in approving any other basis. If, however, the authorities do agree to the change it is fairly certain that no exceptions would be allowed to the bringing in of *all* cash received in the selected year. The argument that tax has already been paid on an item of income earned before but received after March 31, 1941, is of general application, and E would be open to the reply that while the Panel cheque would work against him in the event of a change of basis, other items might work against the Revenue.

LETTERS, NOTES, ETC.

Auscultation in Non-penetrating Abdominal Injuries

Dr. H. P. TAIT (Edinburgh) writes: I was extremely interested in Mr. Th. Schrire's paper on non-penetrating injuries of the abdomen (Aug. 1, p. 127), and noted in particular that he made no mention of the use of auscultation of the abdomen in such cases. The value of this form of diagnostic aid is emphasized in at least one standard textbook of surgery (Romanis and Mitchiner, *Science and Practice of Surgery*, 3rd edition, 2, 508). In view of the importance of early diagnosis of such difficult cases, I would be glad to hear of other opinions on the value of auscultation in such cases as may be met with in A.R.P. work.

Treatment of Plantar Warts by Elastoplast

Dr. H. HUGHES JONES (Nevin) writes: I was interested to read Dr W. Hirst Bateman's medical memorandum on the treatment of plantar warts by elastoplast dressings (Aug. 8, p. 158). I have used a similar dressing for some years with gratifying results. My method is as follows. A first dressing of elastoplast is put on, with a perforation therein for the wart to protrude. This is covered by a second layer of elastoplast and left intact for about 21 days. By this means pressure from footwear is minimized, and the relief from pain experienced by the patient is most welcome. The dressing is generally renewed in 21 days, and the wart disappears in from 6 to 8 weeks.

Plague

Dr. S. A. MONTGOMERY (Bournemouth), in the course of a letter, writes: In your Nova et Vetera column on July 25 the short article written by Lieut.-Gen. Sir W. P. MacArthur must have been read by many like myself with much interest and instruction. Plague, everyone knows, is endemic in India, and with that country so near our shores by air the practitioner might any day be confronted with a case that had passed through the airport medical officer's hands before the disease had fully developed or the incubation period was completed. The incubation period of plague is comparatively short, and so the disease has not time to incubate fully on the journey by air. In a paper read at a health congress at Belfast in 1932 Dr. W. M. Frazer, port medical officer, Liverpool, stated that an outbreak of human plague occurred as recently as 1910-11, when four cases were reported, contracted from hares infected by rats in East Suffolk. The outbreak was very restricted, and the number of fleas in East Suffolk that winter scanty—averaging under one flea per rat—and the *Xenopsylla cheopis* was absent, so that conditions for rapid infection of human beings were not present.

Action of the Heart under Anaesthesia

Dr. P. GOLDSCHEIDER (Enfield) writes: In your leading article (July 18, p. 73) you say that Dr. John Elam made a useful suggestion that "the Association of Anaesthetists might carry out an investigation into the relative safety of the various anaesthetics now used in general surgery and so lead to an assessment of their indications and contraindications" May I remark that at least part of the toxic influence of the various anaesthetics—namely, the influence on the heart—can be investigated by a strictly objective method by taking electrocardiograms of patients while under an anaesthetic. Different authors have made such tracings. I have made quite a number with ethyl chloride, ether, pentothal, and gas and oxygen anaesthesia. The results show that all the various anaesthetics influence the heart by producing arrhythmias, extrasystoles, changes in the appearance of the T-wave, depression of the S-T stretch, etc. This influence is usually quite transient, but I was induced to make this investigation years ago by finding a pathological electrocardiogram in a formerly quite healthy young man 3 months after appendicectomy. Investigations on a large scale would certainly make a valuable contribution in the assessment of the indications and contraindications of the various anaesthetics.

Nomenclature of Night-blindness

Dr. FRANCIS E. PRESTON (London, E.11) writes: I thank Dr. J. Price Williams (Aug. 1, p. 148) for his healthy constructive criticism of that portion of my article dealing with this subject. The word "nyctamaurosis" was carefully considered by me, but was turned down for the following reason. Amaurosis is an established word with a precise meaning. Neame and Williamson-Noble, in the glossary contained in the 1942 edition of their *Handbook of Ophthalmology*, define it as a serious defect of vision without any visible disease of the eye "Nyctamaurosis" can only indicate those defects of night vision where there are no external or ophthalmoscopic signs of disease. How, therefore, are we going to express the state when there are signs of disease? "Nyctamauroma," being a new word, can cover both conditions.

MEDICINE 100 YEARS AGO

Extract from a leading article in the *Provincial Medical Journal*, September 3, 1842:

"It is thought by some of the advocates for a reform of the abuses which disgrace the whole of our medical polity, that a revision of the system of education should form a part of any legislative measure which may be brought forwards to receive the sanction of Parliament. . . . The first object of medical education is to prepare such a number of well-qualified practitioners for the public service as the wants of the community require. Medical practitioners well grounded in the principles of the profession, and capable of treating, as they arise, cases of disease, external or internal, are what are wanted for the care of the public health. To be an accomplished literary scholar, or an acute mathematician; to be well acquainted with botany or zoology, or even to be thoroughly instructed in chemistry, anatomy, and physiology; are of no avail if the practical application of these preliminary studies to the cultivator of medicine or surgery be wanting. Whatever importance, therefore, may attach to certain of these branches of knowledge, and we are far from underrating their value, they can be considered only as preparatory to the main object of qualifying the candidate for the due performance of his medical duties. . . . But, at the same time that every provision should be made for adequate medical instruction, we would not be understood to advocate the drawing of the reins of academical discipline so tight as to place the intelligent student in trammels, which, while they compel his attention to certain prescribed studies in a certain prescribed order, often prevent him from giving that free course to his natural talent which would enable him to arrive at the same end with more satisfaction, as well as with less labour to himself, or force on his mental faculties. The cultivators of medicine ought never to forget that some of the most eminent individuals, whose names are preserved in the records of their science, have been self-educated."

*** The *Provincial Medical Journal* subsequently became the *British Medical Journal*.

PLASMA PROTEIN CONCENTRATION AFTER HAEMORRHAGE

BY

J. BEATTIE, M.D., D.Sc. AND H. B. COLLARD,* B.A.

(*From the Bernhard Baron Research Laboratories, Royal College of Surgeons of England*)

After haemorrhage the blood volume is rapidly restored to its pre-haemorrhage level in cats (Robertson, 1935) and more slowly in human subjects (Stead, 1940 ; Wallace and Sharpey-Schafer, 1941) and in dogs (Price *et al.*, 1941). It is generally assumed that the fluid from the tissue spaces which enters the blood stream to restore the blood volume is weak in plasma proteins. These substances have been shown by Madden and Whipple (1940), in long-term experiments, to be replaced either from existing plasma protein stores or from protein synthesized from ingested foodstuffs. There are few data, however, on the replacement of plasma proteins from existing stores in the early hours after haemorrhage. The experiments recorded here throw some light on the movement of plasma protein into the blood stream during the first 2 hours after known quantities of blood had been withdrawn from the circulation.

TABLE I.—*Haemoglobin (Hb) and Plasma Protein (P.P.) Concentrations after Haemorrhage*

Methods

Cats anaesthetized with nembutal injected intraperitoneally (50 mg. per kg. of body weight) were used. After induction 4 hours was allowed for stabilization of blood volume before an experiment was started. The animals were heparinized during an experiment, and blood or plasma from heparinized animals was used for transfusions. Blood samples of 1 c.cm. and blood for haemorrhage were taken from a femoral artery, while transfusions were given by a femoral vein. Haemoglobin was estimated in 0.05-c.cm. samples by the alkali–haematin method, using a photo-electric colorimeter. Plasma specific gravities were estimated by the falling-drop method of Barbour and Hamilton (1926). Plasma protein values were deduced from the plasma specific gravities, using the formula of Weech *et al.* (1936), or determined direct by the biuret method of Robinson and Hogden (1940).

Observations

Single Haemorrhages

The changes in haemoglobin and plasma protein concentrations after 20% haemorrhages are shown in Table I. If it be assumed that all erythrocytes discharged from "stores" during and after the haemorrhage find their way into the circulation and are thoroughly mixed when the 30-minute samples are taken, then the subsequent falls in haemoglobin concentration would be due to movement of fluid into the blood stream. If no new protein enters the blood stream, then the ratio of haemoglobin concentration at the 30-minute sample to the haemoglobin concentration in a subsequent sample would be identical with the ratio of the plasma protein concentration at the 30-minute sample to the plasma protein concentration in the same subsequent sample—e.g.,

$$\frac{\text{Hb conc. (30 min.)}}{\text{Hb conc. (75 min.)}} = \frac{\text{Pl. protein conc. (30 min.)}}{\text{Pl. protein conc. (75 min.)}}$$

Calculating the expected plasma protein concentration at the 75-minute samples, which allow slightly more than 1 hour after the end of the haemorrhage, the values in Table II, column 3, are obtained. Similarly, the expected values for plasma protein concentration are calculated for the last sample in each experiment. These are given in Table II, column 6.

A comparison of the expected values at 75 or 90 minutes in column 3 with the observed values in column 2 shows that 4 out of 5 animals had expected values lower than those observed, and one animal had observed and expected values almost identical. The expected and observed values at the end of each experiment are shown in Table II, columns 5 and 6. The animals which showed expected values lower than the observed ones at 75 or 90 minutes show a lower expected value at 105 or 135 minutes than that observed. The observed and expected values in Cat 103 were almost identical. Cat 64 differed from the rest of the experiments in this group. Dilution had progressed from 87.2 to 76.1 haemoglobin concentration, but the fall in plasma protein concentration was greater than that to be expected from the fall in haemoglobin.

TABLE II

---

* Leverhulme Scholar, Royal College of Surgeons of England

Haemorrhages followed by Blood Transfusions

The animals in this series (5) were bled, and after varying times had the blood which had been removed reinjected. The quantity reinjected approximated closely to that removed (Table III). At the end of the period allowed for dilution—75 or 90 minutes (except Cat 131)—the differences between the expected and observed values for plasma protein were small, with one exception in which the values were identical. The observed values were slightly higher in 3 out of 4 animals (Table IV, columns 4 and 5). After the reinjection of the blood the experiments were continued for at least an hour. In every experiment the amount of plasma protein expected from changes in haemoglobin concentration was greater than that actually observed (Table IV, columns 6 and 7).

Cat 131 had its blood returned 30 minutes after haemorrhage. The observed value for its plasma protein was less than the expected value by a considerable margin 1 hour after the reinjection.

* Plasma transfusion of 30 c.cm. at 63 minutes before haemorrhage

Haemorrhages followed by Plasma Transfusions

The observations are shown in Table V. Cat 67 was given plasma of a lower protein content than that of its own plasma before haemorrhage. Before the plasma transfusion the observed and expected plasma protein concentrations were almost identical (Table VI, columns 3 and 4). At the end of 75 minutes after the transfusion the observed plasma protein concentration was less than that expected (Table VI, columns 5 and 6). The amount of plasma given to this animal was less than one-third of the volume of blood removed. Cat 101 was bled 50 c.cm. and given 40 c.cm. of plasma with a high protein content (7.89 per 100 c.cm.) 15 minutes after the end of bleeding. The expected plasma protein concentration at the end of the experiment was higher than that observed (Table VI, columns 5 and 6). Cat 107 was bled 60 c.cm. and given only 20 c.cm. of plasma with a protein content of 5.85 g. per 100 c.cm. 30 minutes after the end of bleeding. At the end of 105 minutes after the transfusion the observed plasma protein concentration was less than that expected (Table VI, columns 5 and 6).

Cats 89 and 90 were given plasma transfusions equal to half the volume of the subsequent haemorrhage about 45 minutes before bleeding was started. Cat 89 was bled 30 c.cm. and given 15 c.cm. of plasma with a protein content of 6.87 g. per 100 c.cm. 1 hour after haemorrhage. The observed value of plasma protein concentration was considerably greater than that expected immediately before transfusion (Table VI, columns 3 and 4). Forty-five minutes after transfusion the observed value was only slightly lower than that expected (Table VI, columns 5 and 6). Cat 90 was bled 38 c.cm. and given 19 c.cm. of plasma with a plasma protein content of 7.35 g. per 100 c.cm. 65 minutes after haemorrhage. Before the plasma transfusion the observed value of plasma protein concentration was slightly higher than that expected (Table VI, columns 3 and 4); 45 minutes later the observed plasma protein level was higher than that expected (Table VI, columns 5 and 6).

* Plasma transfusion before haemorrhage: Cat 89 received 15 c.cm. at 43 minutes before haemorrhage, and Cat 90 received 19 c.cm. at 48 minutes before haemorrhage.
† Plasma transfusion after haemorrhage: Cats 101 and 107 received plasma at 15 and 30 minutes after haemorrhage.

Discussion

The necessity for eliminating the influence of erythrocytes added from "stores" is the reason why it is not possible in these experiments to make a comparison between the haemoglobin and plasma protein values before haemorrhage with those subsequent to bleeding. As it has been shown (Ebert and Stead, 1941) that in man no such stores exist comparable to the spleen of the dog and cat, it is possible to use in human experiments the pre-haemorrhage values for comparison with those after bleeding. Wallace and Sharpey-Schafer (1941) have published observations on plasma protein concentrations with simultaneous haemoglobin concentrations in convalescent human subjects bled varying amounts from 1,150 to 465 c.cm. In their series, 17 subjects had their plasma protein concentrations estimated before haemorrhage and also either at the end of bleeding or after 1 hour, or both. Twelve subjects were also examined for plasma protein concentration at the time of maximum dilution. Calculating the expected plasma protein concentration from the haemoglobin values, the figures set out in Table VII, columns 8, 11, and 15, were obtained.

TABLE VII.—*Effect of Haemorrhage on Haemoglobin and Plasma Protein Concentration in Man. Compiled from Data given by Wallace and Sharpey-Schafer (1941)*

Eleven subjects had plasma protein concentrations determined after haemorrhage. Of these, 8 (Nos. 1, 3, 11, 14, 16, 19, 26, 27) showed an excess of plasma protein over that expected as calculated from the haemoglobin concentrations, 2 (Nos. 9, 21) had observed and expected values in close agreement, and 1 (No. 23) showed a protein value less than that expected. The amount of protein produced in excess of that expected was not correlated either with the amount bled or with the time taken for bleeding. After 1 hour, 3 (Nos. 5, 8, 25) out of 6 subjects showed observed values in excess of that expected, 2 (Nos. 18, 23) had observed and expected values closely similar, and 1 (No. 7) had an expected value in excess of that observed. There was again no correlation between bleeding time, the amount of blood withdrawn, and the amount of protein in excess of the expected value. At the time of maximum dilution 13 subjects showed observed values in excess of that expected. Four of the 17 subjects were not observed for plasma protein concentration at this period. There was no correlation between the time taken to reach maximum dilution and the amount of protein in excess of that expected.

There is clear evidence, therefore, that in man plasma protein in considerable quantities can enter the blood stream during the actual haemorrhage, which may be as brief as 10 minutes or as long as 24 minutes. The fact that there is no correlation between the amount of protein entering the blood stream and either the bleeding time, the amount bled, the duration of active dilution of the blood, or blood pressure changes or the duration of such changes, suggests strongly that these factors are not concerned in the movement of protein into the blood stream, whether in small quantities contained in the actual fluids entering the blood stream from the tissues or in larger quantities entering it from some specific protein store such as the liver.

When these human results are compared with those obtained in the series of experimental animals recorded above, the same variations between observed and expected plasma protein values are found. Four out of 6 animals (Table II) showed evidence of plasma protein production, 1 showed no evidence of such production, and 1 showed a plasma protein concentration less than that expected. Of the 4 animals observed towards the end of the second hour or the beginning of the third hour after haemorrhage, 3 showed values in excess of that expected, and 1 slightly lower than that expected. The latter animal was that which had shown no change 75 minutes after haemorrhage.

It would appear, therefore, that what is being observed both in man and in the experimental animals might be related to the amount of protein "in store" in the individual animals. Hence those animals with poor reserves of protein would show a close approximation of expected and observed plasma proteins, while those with a depleted store might be expected to show an observed plasma protein value less than that expected. It is obvious that the magnitude of the effects of haemorrhage on plasma protein concentration is much greater in the human series than in the animals. This may be in part due to the fact that while in man it is possible to compare pre- with post-haemorrhage values, that cannot be done in cats owing to the unknown number of erythrocytes liberated from the blood stores. Splenectomy in cats diminishes considerably but does not eliminate the storage capacity for red blood cells.

When blood is reinjected into animals which have been bled, the blood volume is increased considerably above the pre-haemorrhage level immediately after transfusion. This is due, of course, to the fact that dilution had progressed considerably before transfusion, and the reinjection of the blood withdrawn produces an increased blood volume. The changes in haemoglobin values (Table III) show clearly that in 3 animals out of 5 there must have been considerable reinforcement of the red cell population from erythrocyte stores. The 2 animals remaining show that their stores must have been either depleted before haemorrhage or were inactive during and after bleeding.

The increased blood volume undergoes reduction in all the animals after blood transfusion, as is shown by the rise in haemoglobin values. At the same time it will be noted that the change in haemoglobin value is not paralleled by a similar change in plasma protein concentration: the expected values are in each experiment higher than those observed. This suggests that the movement of fluid out of the blood stream is accompanied by a movement of protein out of the circulation. It is significant that in these 5 experiments (Tables III and IV) the amount of protein contributed to the blood after haemorrhage was small, which might, as suggested above, indicate poor reserves of protein. This view is supported by the fact that in all these animals the outward movement of protein after blood transfusion was well marked, except in Cat 124. Cat 126, which had had a preceding plasma transfusion (63 minutes before haemorrhage), must have had poor protein reserves, as it was not able to mobilize any significant quantity of protein after haemorrhage. The same animal depleted its circulating plasma protein considerably after its blood transfusion.

In the third series of experiments, plasma was transfused after haemorrhage. Two animals (89 and 90) had plasma transfusions at about 45 minutes before haemorrhage. One of these animals (89) added protein to the blood after haemorrhage in sufficient quantity to produce a plasma protein concentration of 7.96 as compared with an expected value of 7.41 g. per 100 c.cm. This may be interpreted as showing that the animal had an adequate protein reserve. This is confirmed when the expected and observed values after plasma transfusion are examined. They are almost identical. On the other hand, the second animal (90), which showed a small addition of plasma protein after haemorrhage, added a considerable amount of protein to the circulation after its second (post-haemorrhage) plasma transfusion. All the other animals (67, 101, and 107), which had had no plasma transfusion previous to haemorrhage, showed lower observed values than those expected. It would seem, therefore, that movement of protein out of the circulation was to reinforce the plasma protein reserves.

An Important Factor

It is obvious from the animal experiments that the state of the plasma protein stores—whether adequate or depleted—must be the most important factor in determining the amount of protein entering the circulation after haemorrhage and also in deciding the rate at which this addition is made. If the stores are depleted completely, then the plasma protein concentration after haemorrhage will be less than that expected, as the protein requirements of the body must be met from the circulating plasma protein. The gap between expected and observed values will continue to widen unless new protein is added direct to the blood by blood or plasma transfusions or is synthesized from the breakdown products of protein taken by mouth.

If the adequate stimulus to movement of protein into the blood stream is a low plasma protein content of the blood, then some correlation might be expected between the degree of protein deficit (difference between plasma protein values before and 30 minutes after haemorrhage) and the amount of protein entering the blood stream at, say, the end of 1 hour after haemorrhage, indicated by the difference between the expected and observed plasma protein values. Such a correlation does not exist. Consequently, it would seem that either hypoproteinaemia is not the adequate stimulus or, alternatively, such stimulus is effective only when protein reserves exist outside the blood stream. The balance of evidence so far would suggest that the latter view is more likely to be correct. It is not suggested, however, that the protein in the plasma stores exists precisely in the form of the albumin–globulin complex present as plasma protein in the blood. The speed with which protein does appear in the blood stream and the amounts contributed after haemorrhage lend strong support to Whipple's view that the precursor of the plasma proteins in the plasma protein stores requires very little change before it can be discharged across the cell membrane into the blood stream.

The state of the protein reserves of the body may be determined by the response to plasma transfusions. After allowing 15 minutes for thorough mixing of the infused plasma, a blood sample is taken, followed by further samples at 45 and 75 minutes after the end of transfusion. The movement of the haemoglobin values is determined, and from these are calculated the expected plasma protein value for the 45-minute and 75-minute samples. If the observed values are greater than those expected it can be concluded that the movement of protein from blood to body cells is slow, and presumably protein stores are adequately filled. If the expected and observed values are equal or approximately equal, then protein-free fluid only is moving out of the blood stream. If the expected value is greater than the observed value, then protein movement from the circulation is rapid, and unless there are signs of massive protein movement into the tissue fluid—e.g., oedema—it must be presumed that the plasma protein stores are low. Such results give a useful indication of the state of the protein stores

Conclusion

It is clear from these experiments that after haemorrhage the restoration of blood volume is independent of the restoration of plasma protein. Restoration of both concurrently would imply considerable protein stores. The speed of blood volume restoration in the cat apparently always outstrips the rate of plasma protein movement into the blood stream. In man the data of Wallace and Sharpey-Schafer make it clear that even after large haemorrhages (1,150 c.cm.) the plasma protein concentration can remain unchanged, although blood dilution is proceeding rapidly. One subject (19) apparently restored his blood volume after a haemorrhage of 750 c.cm. within 4 hours, and at the end of that time had increased his plasma protein concentration from 6.6 to 6.9 g. per 100 c.cm. This subject had a blood volume of 4 litres before haemorrhage and one of 4.2 litres after haemorrhage.

After haemorrhage and subsequent dilution of the blood, a blood transfusion is followed by a rapid increase in haemoglobin concentration. This haemoconcentration is not pathological but is due entirely to fluid movement out of the blood stream. The restoration of the blood volume to its pre-haemorrhage level takes place independently of a movement of erythrocytes into the blood stores or of plasma proteins out of the circulation. A movement of erythrocytes out of active circulation after blood transfusion would give an expected plasma protein value lower than the observed value. The fact that no animal showed such excess of observed plasma protein over that expected even more strongly suggests that there had been rapid movement of plasma protein out of the circulation.

Summary

There is evidence of movement of plasma proteins into the blood stream within 2 hours after haemorrhage in cats anaesthetized with nembutal.

Blood transfusions at varying times after haemorrhage are followed by movement of plasma proteins out of the circulation within 1 hour of completion of transfusion.

Plasma transfusions after haemorrhage are followed by plasma protein movement out of the circulation within 1 hour of completion of transfusion.

The rate and amount of plasma protein movement into the circulation are independent of the amount or rate of bleeding, the amount or rate of dilution by fluid from the tissue spaces, and blood-pressure changes.

The amount of plasma protein contributed to the blood, and therefore the plasma protein concentration at any time after haemorrhage (provided no food containing protein has been administered), is probably dependent on the state of the plasma protein stores outside the circulation.

A method of testing the adequacy or otherwise of plasma protein stores is suggested.

We wish to thank Drs. Wallace and Sharpey-Schafer for permission to use the data in Table VII, and for allowing us to inspect some of their unpublished results.

CIRCULATORY OVERLOADING FOLLOWING RAPID INTRAVENOUS INJECTIONS

BY

E. P. SHARPEY-SCHAFER, M.R.C.P.

AND

JOHN WALLACE,* B.Sc., M.B.

WITH TECHNICAL ASSISTANCE OF

A. LATHAM AND A. C. PINCOCK

(From the Department of Medicine, British Postgraduate Medical School)

Authorities differ widely in advising the amount of serum or blood to be injected and the rate at which it should be given. Many stress the dangers of overloading the circulation. In 1894 Bayliss and Starling showed that rapid injection of crystalloid solutions or blood caused a rise of venous pressure, observations which have been amply confirmed by others in the experimental animal (Bainbridge, 1915; Wiggers, 1921). Meek and Eyster (1922) showed in dogs that the immediate effect of an intravenous injection was a rise of venous pressure associated with an increase in the diastolic size of the heart; these effects were only transitory, and there was evidence that the peripheral capillaries and venules were acting as reservoirs. There have been fewer observations in man. Eyster and Middleton (1924) investigated 4 normal subjects. In the case showing the most pronounced change 600 c.cm. of blood was given at the rate of 43 c.cm. a minute; this produced a rise in venous pressure of 2 cm. H_2O but no increase in the size of the heart. Caughey (1935) found no rise of venous pressure in normal subjects receiving 1,500 c.cm. of saline at the rate of 50 c.cm. a minute, while a rise of up to 6 cm. H_2O was produced in some patients with heart disease. No attempt was made to measure the degree of retention of injected saline in the circulation. Altschule and Gilligan (1938) gave from 500 to 1,500 c.cm. of crystalloid solutions to 35 subjects at rates of 6 to 71 c.cm. a minute. The venous pressure was raised more than 4 cm. H_2O in only 6 subjects, pulse and blood-pressure changes were small, the cardiac output was increased, but there was no change in vital capacity. This paper reports the results of rapid intravenous injection of saline, serum, and, in a few cases, blood on the venous pressure and certain other cardiovascular measurements.

---

* Working for the Medical Research Council.

Methods

The observations were made on convalescent subjects without cardiovascular disease. The conditions of study have been given elsewhere (Sharpey-Schafer and Wallace, 1942). The haemoglobin was estimated on 0.02 ml. freely flowing ear samples by a photo-electric method (Hill and Pincock, 1941). Venous pressures were estimated in the antecubital vein by a continuous citrate method (Wood, 1940), and changes were checked by direct observation of the neck veins (Lewis, 1937). Up to 45 minutes may have to be allowed for the venous pressure to reach a steady level. Vital capacity was measured on a Benedict-Roth spirometer. Radiographs of the heart were taken in the sitting posture, with the tube at 6 ft. The exposure was 1 second to obtain the diastolic heart size. Differences in inclination or respiratory excursion are indicated in the text. Usually two control and several post-injection films were taken. The right pectoral–F or the right pectoral–R leads (Wood and Selzer, 1939) were employed in the electrocardiographic studies. The following solutions were used: (1) 0.9% saline; (2) normal strength reconstituted lyophil serum; (3) 4-times-concentrated reconstituted lyophil serum; (4) citrated blood.

Results

The results are shown in Table I. When the rate of injection was between 50 and 150 c.cm. a minute the venous pressure began to rise after about 1,000 c.cm. of saline or serum had been given, and reached a maximum toward the end of injection (Fig. 1). If the rate of injection was very rapid, as little as 500 c.cm. raised the venous pressure. The subject shown in Fig. 2 received the first 500 c.cm. of serum

* Blood.

at a rate of 250 c.cm. a minute. All subjects given saline or serum showed a rapid fall of venous pressure once the injection had been stopped. Saline often left the circulation quickly, as indicated by a rising haemoglobin percentage (Fig. 1). The venous pressure still fell in a matter of minutes, however, if the haemoglobin remained at the lower post-injection level (Fig. 2). One subject given blood showed a rise of venous pressure that persisted for 50 minutes. When the blood volume was first reduced by a large venesection, injection of serum or saline in similar quantities and at similar rates produced little or no change in venous pressure (Table II and Fig. 3). The subject of Fig. 3 showed a small fall of venous pressure after venesection, associated with a fall of blood pressure and syncope. In this and other subjects with syncope after large venesections (Wallace and Sharpey-Schafer, 1941) a small fall of venous pressure (1 to 2 cm.) preceded the fall of blood pressure, and there was a further fall of venous pressure with collapse of the circulation. If there is no fall of blood pressure after venesection, there is, however, an abnormal fall on sitting upright. Weiss, Wilkins, and Haynes (1937) showed that the fall of blood pressure and syncope in the upright posture after sodium nitrite is preceded by a fall in venous pressure. Injection of serum immediately after venesection restored venous pressure, blood pressure, or postural response to normal. When giving intravenous injections at rates of 100 c.cm. or more a minute considerable pressure must be maintained in the bottle of fluid; measurements of venous pressure in the opposite antecubital vein might therefore merely reflect this transmitted pressure. That this is not so, and that a rise of venous pressure is due to an acutely increased blood volume, is shown by the following considerations: (1) When the blood volume has not been previously reduced a rise of venous pressure does not occur until about 1,000 c.cm. has been given, at rates of about 100 c.cm. a minute. (2) There is a statistically significant correlation between the rise of venous pressure and the fall of haemoglobin (Fig. 4). (3) There is little or no rise of venous pressure when saline or serum is injected immediately after blood-volume reduction by venesection. (4) If, however, enough time elapses after venesection for the haemoglobin to fall considerably, transfusion of similar quantities then causes a rise of venous pressure.

Table II.—*Injection after Venesection*

Case	Age and Sex	Initial Hb%	Amount of Venesection (c cm)	Rate of Venesection (c.cm /mm.)	Hb% Change directly after Venesection	Amount Injected (c.cm.)	Rate of Injection (c.cm./min.)	Immed. Hb% Fall	V.P Change (cm. H_2O)	Symptoms

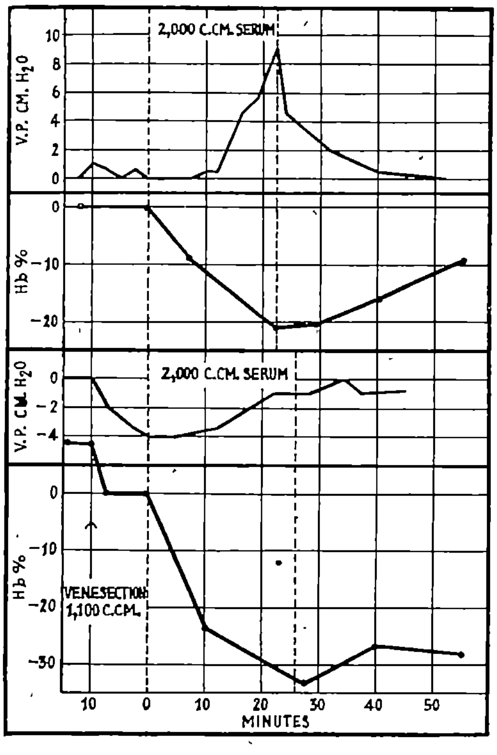

Fig 3.—Case 12a and 12b: interval of 10 days between observations.

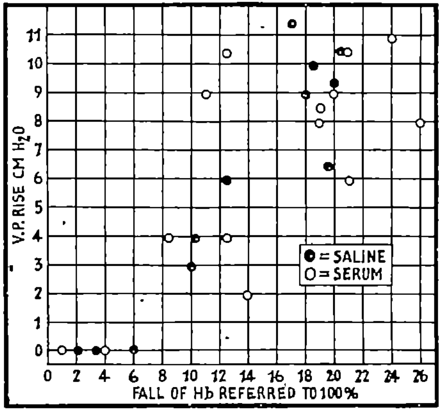

Fig. 4.—Relation between rise of venous pressure and fall in haemoglobin: coefficient of correlation (r)=0.84

Vital Capacity.—The vital capacity, measured within 2 minutes of the end of injection, showed an average fall of 470 c.cm. in 6 of 7 subjects (Table I). McMichael and McGibbon (1939) have shown that there is a fall in the lung volume and vital capacity of normal subjects on assuming the horizontal posture; they ascribed the fall to the presence of more blood in the lungs. Venesection, on the other hand, increases the vital capacity (Glaser and McMichael, 1940). That the fall of vital capacity on overloading the circulation is due to increased blood in the lungs is borne out by the *x*-ray appearances. None of these subjects showed clinical evidence of pulmonary oedema, and the respiratory rate and tidal air showed no change.

Radiograph of Heart.—Films were taken before and immediately after injection. The results are shown in Table III. The area of the cardiac shadow was measured by a planimeter, and the right, left, and oblique cardiac and transverse chest diameters were also measured. In 5 of the 8 subjects examined the average increase in the heart area was 15.3%. Table I shows that there was a considerable rise of venous pressure and fall of haemoglobin in each of these 5 subjects. Although the latter changes were present in Case 2, there was but little cardiac enlargement. So far as could be judged from postero-anterior films the enlargement appeared to involve all chambers. In addition, the following changes were present after injection: the superior vena cava shadow became prominent in those subjects in whom there was a considerable rise of venous pressure, the pulmonary arteries and vascular markings in the lungs increased in size and density, and the whole lung fields were relatively less translucent (Figs. 5 and 6).

TABLE III.—*Radiological Measurements*

Case	Heart Area (sq. cm.)		Right Diam. (cm.)		Left Diam. (cm.)		Oblique Diam. (cm.)		Transverse Chest (cm.)	
	B.	A.	B.	A.	B.	A.	B.	A.

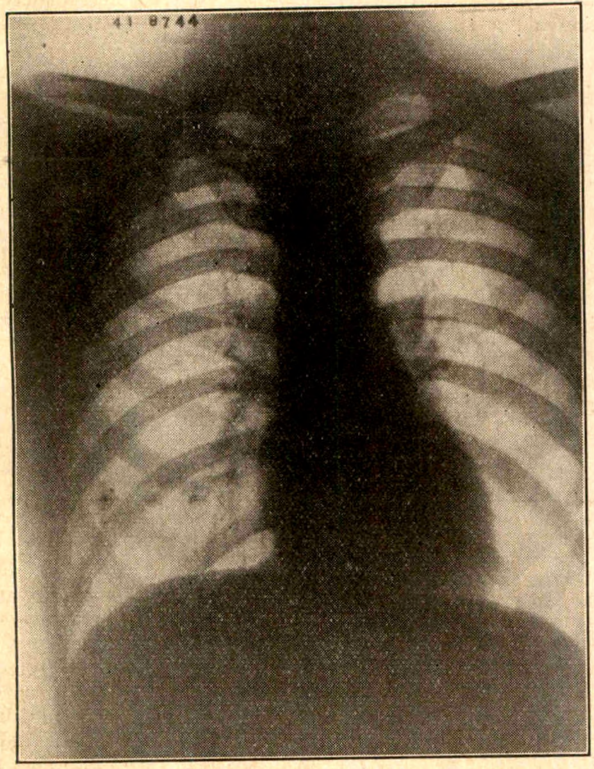

FIG. 5.—Radiograph of Case 14 before transfusion.

Electrocardiogram.—The right pectoral–R arm or right pectoral–L leg electrocardiogram is the chest lead that gives one of the earliest indications of acute right heart stress, as from packed pulmonary embolism (Wood, 1941). Changes in the T-wave are in the direction of inversion when chest leads are recorded in the manner agreed by the Cardiac Society of Great Britain and Ireland and the American Heart Association (*British Medical Journal*, 1938, **1**, 187). Only 4 of 12 subjects showed electrocardiographic changes, the T-wave becoming flattened or inverted. Gilligan and Altschule found increased amplitude of the P-wave in lead II in a few of their cases.

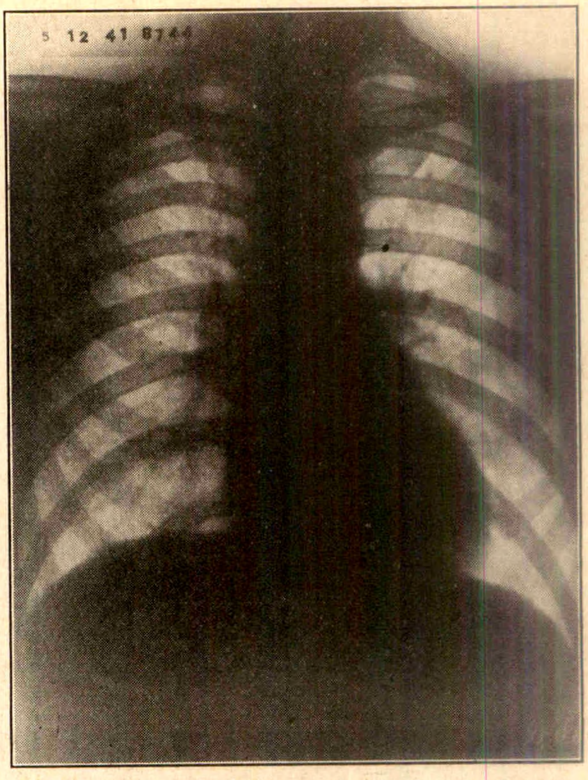

FIG. 6.—Radiograph of Case 14 after 1,200 c.cm. of serum.

There were no P-wave changes in leads RP–R or F in this series. The x-ray findings suggest that enlargement of the heart shadow may involve all chambers in some subjects. Electrocardiographic changes in the direction of preponderance of ventricle would therefore not be expected, since it is well known that cardiac enlargement can take place without them. However, it has not proved possible so far to observe the correlation, if any, between electrocardiographic changes and x-ray appearances after acute overloading of the circulation.

Heart Rate.—The heart rate showed no change or slowing in 9 subjects, while 6 showed an increase.

Symptoms.—Eight subjects had headache; 4 complained of a feeling of constriction in the chest during injection; in 1 it was severe, but not severe enough to necessitate termination of the injection. It passed off rapidly as soon as intravenous fluid was stopped. The most striking sign was vasodilatation; it was present in all subjects with any degree of retention of saline or serum in the circulation. The face became redder in tint, and the peripheral veins became prominent and distended.

Summary

Up to 2,000 c.cm. of saline, serum, and blood was injected into subjects without cardiovascular disease at rates of from 54 to 168 c.cm. a minute. The venous pressure was raised up to 11 cm. H_2O when there was considerable retention of injected fluid in the circulation, as indicated by the fall in haemoglobin. Radiographs showed an increase in the diastolic size of the heart, enlargement of the pulmonary arteries, and prominence of the vascular markings in the lung fields. Vital capacity was diminished, but there was no evidence of pulmonary oedema. In spite of the rise of venous pressure many subjects had no increase in heart rate. Of 12 subjects 4 showed electrocardiographic changes indicating slight right heart stress. Symptoms were absent or unimportant. There was a rapid fall of venous pressure to normal on ceasing injection, except in one subject given blood. There is evidence that the peripheral and pulmonary capillaries and veins dilate to accommodate the increased blood volume.

When the blood volume was first reduced by a large venesection, saline or serum injected in similar amounts and at similar rates caused little or no rise of venous pressure.

We thank Dr. Janet Vaughan for supplies of serum, and Drs. Duncan White and E. J. E. Topham for their help with the radiological measurements. The work was assisted by an expenses grant from the Medical Research Council.

SULPHONAMIDE SUNLIGHT ERUPTIONS

A CLINICAL STUDY OF 27 CASES

BY

R. G. PARK, M.B., M.R.C.P.
Captain, N.Z. Medical Corps

AND

W. M. PLATTS, B.Sc., M.B., Ch.B.
Captain, N.Z. Medical Corps

(From a Military Hospital in the Middle East)

The constant sunshine of the Middle East and the presence of considerable numbers of V.D. patients undergoing ambulant chemotherapy in an open-air tented hospital have recently given us unusual opportunities of observing cases of the light-sensitive type of sulphonamide dermatitis.

This form of dermatitis has been classified into two varieties (Tedder, 1939): generalized eruptions showing no predilection for the exposed parts, and light-sensitive eruptions. It is with the latter that this report is concerned.

Cases of sulphonamide photosensitivity were first recorded in 1937 (Newman and Sharlit, 1937; Menville and Archinard, 1937), rashes being described which appeared after from 3 to 5 days of drug therapy and which disappeared after 5 or 6 days of protection from light. Severe dermatitis has also occurred from artificial ultra-violet irradiation during sulphapyridine administration (Hallam, 1939). On the analogy of the sunlight eruptions in haematoporphyrinuria, investigation has shown that sulphonamides cause an excessive urinary excretion of porphyrins, of which one, coproporphyrin I, is a recognized photosensitizer (Rimington and Hemmings, 1938). This occurs more often with sulphanilamide than with sulphapyridine (Wien, 1938). The porphyrinuria varies considerably with the individual, and by exposing unselected patients on sulphanilamide Eidinow (1939) has shown that by no means everyone becomes light-sensitive.

Case Reports

During the 12 months Oct., 1940, to Sept., 1941, 486 cases received sulphanilamide, of which 21 developed eruptions (4.3%); 309 cases received sulphapyridine, yielding 6 eruptions (1.9%). Of the 27 cases 8 occurred during July and 6 during August. As measured by the photo-electric cell, the intensity of visible light in this part of the Middle East in July is about four times that in January. We have divided our cases into two groups:

1. Eruptions Limited to Parts Exposed to Sun during Chemotherapy

There were 17 cases of this kind, 16 with sulphanilamide and 1 with sulphapyridine. In 5 cases the rash appeared on the eighth day of chemotherapy, in 5 on the ninth, and in 7 on the tenth. The eruption consisted of maculo-papules in a morbilliform or roseoliform configuration. It was confluent on the most exposed parts, being distinguished from sunburn only by the discrete lesions at the margins. The demarcation was very sharp at places such as the singlet area or, where no shirt had been worn, the waist. The axillae were usually spared. The bronzed parts—face, neck, forearms, hands—suffered less than the upper trunk and upper arms, which had been exposed less in the past. Two patients admitted to unusually heavy sun exposure the day before the rash began. Only 5 of the 17 had always sunburned easily.

In addition to the above lesions there was in one case vesiculation and pustulation of the face, in 2 oedema of the hands, and in another oedema of the eyelids. Itching varied from severe to none at all. In one case—an eruption limited to the hands—an experimental exposure of the forearms to the sun was made for 3 hours on the third day of the rash. After an hour a maculo-papular eruption appeared in the exposed area, maximal on the non-bronzed flexor surfaces. In another case, in addition to a roseoliform eruption, the dorsum of the hands showed typical target patches of erythema iris at the sites of some old scars, and the face developed oedema and pustules, going on to extensive desquamation.

Constitutional disturbance was common, fever up to 102° and malaise occurring in half the cases and three rigors in one case. The eruptions faded rapidly—in 2 to 4 days in all cases except one, which lasted a week. Three patients continued chemotherapy for from 1 to 2 days after the rash appeared, with no ill effects, though they kept out of the sun. In one case the rash began 2 days after the drug had been stopped, and in the remainder cessation of the drug either coincided with or occurred on account of the rash.

Of these 17 cases 3 received further chemotherapy at later dates, varying from 1 week to 4 months afterwards. In no instance did the eruption recur, although there was no change in the amount of sun exposure.

2. Eruptions Maximal on Exposed Parts, but also Affecting Others

Case 1 received sulphanilamide for non-specific urethritis, 4 g. daily for 8 days, during which the patient went in the sun with only the face and hands exposed. He had always sunburned easily. On the eighth day an irritable morbilliform rash appeared on the arms, face, and trunk above the waist, principally on the upper part of the back. There was mild cyanosis but no fever.

Case 2 received sulphanilamide for chancroid, 4 g. daily, until it was stopped on the eighth day because of a morbilliform and roseoliform rash, resembling the cases in group 1 except that patches appeared on both thighs over the trochanters. It was slightly itchy, and less pronounced on the bronzed parts. The patient had not previously been sensitive to sunlight. The rash lasted 4 days and was accompanied by a fever up to 103°.

Case 3 received sulphanilamide for chancroid, 4 g. daily for 10 days, during which he went in the sun wearing an open-necked shirt, elbow-length sleeves, long trousers, and rubber shoes. He has always sunburned easily. On the ninth day he developed a slightly itchy morbilliform rash, confluent on the necklace area, back, and outer upper arms. It was also present on the bronzed parts to a lesser degree. Except for a small patch over each great trochanter no rash appeared below the waist. There was no fever or malaise. The rash lasted 3 days.

Case 4 received sulphapyridine for gonorrhoea, 26 g. in 7 days. He had always sunburned easily. On the fifth day he took an open-air shower-bath in the sun, but was otherwise in bed until the seventh day, after which he went out in an open-necked shirt, long trousers, and shoes without socks. On the tenth day a morbilliform and roseoliform rash began. It was confluent on the face, forearms, and dorsum of the feet; discrete on the knees and trunk above the waist; and scanty on the trunk below the waist, upper arms, thighs, and legs. The bronzed parts suffered equally with the others. Itching was slight. The patient was afebrile, but complained of backache. The rash faded in 5 days.

Case 5 received sulphapyridine for gonorrhoea, 26 g. in 7 days. There had been no previous sensitivity to the sun. On the ninth day a dusky-red morbilliform eruption appeared, maximal on the shoulders and outer arms, less marked elsewhere, and especially scanty on the bathing-drawers area and in the axillae. The face was unaffected, but the other bronzed parts suffered equally with the remainder. There had been exposure during chemotherapy. The rash faded in 3 days. A low fever, malaise, vomiting, and headache occurred for 2 days with the rash.

Case 6 received sulphapyridine for gonorrhoea, 26 g. in 7 days. Sun exposure during this time was slight. He had never been sensitive to the sun. On the eighth day a morbilliform rash appeared; this was not itchy. It was confluent on the back, chest, and outer upper arms. Below the waist it was scantier, with a cluster of lesions over each trochanter. There was little if any involvement of the bronzed parts—face and forearms—or of the legs. It faded in 3 days. On the seventh, eighth, and ninth days he had a fever up to 103°, with headaches, backache, anorexia, and conjunctivitis. This was considered to be phlebotomus fever, an epidemic of which was raging at the time.

Case 7 received sulphapyridine for non-specific urethritis, 4 g. daily for 8 days, most of which time he was in bed, but sometimes up in a shirt with elbow-length sleeves and long trousers. He denied being in the sun without a shirt in the past 2 months. He had never sunburned easily. On the eighth day an itchy maculo-papular rash appeared, lasting 3 days. It was generalized—being maximal on the back above the waist and the forearms, and minimal in the axillae. The temperature rose to 99.4°.

Case 8 received sulphapyridine for gonorrhoea, 26 g. in 7 days. Sun exposure and previous sun sensitivity were denied. On the eighth day the patient developed a roseoliform eruption, very itchy, and confluent on the outer upper arms and the trunk above the waist. It also involved the trunk below the waist, the arms and legs, most of the lateral pelvis, and thighs, ankles, and dorsum of the feet. Accompanying this was a suspected attack of phlebotomus fever.

Case 9 received sulphanilamide for non-specific urethritis, 3 g. daily for 10 days. There had been little exposure to the sun. Previously he had always sunburned easily. On the eighth day a rash appeared, consisting of maculo-papules running together into an erythema with wheals in it. The configuration was morbilliform and in places circinate. There was itching. The rash was maximal on the face, neck, upper trunk, forearms, and dorsum of the hands. It was present on the lower trunk, palms, legs, and thighs over the trochanters; but was absent from the bathing-drawers area and the left wrist, where a watch was worn. The exposed parts were not spared. The rash faded in 8 days, desquamation occurring on the face from the fifth day onwards. For 5 days he had malaise, fever up to 101°, and a distinct air-hunger.

Case 10 received sulphanilamide for a tonsillitis of 2 days' duration. The last exposure to sunlight had been 3 days previously, in shirt and shorts. He had never sunburned easily and was accustomed to going about in singlet and shorts. For 2 days 1 g. of the drug was given 4-hourly. On the evening of the first day a rash appeared on the upper trunk and upper arms, and then spread all over. Seen for the first time on the fourth day, the eruption consisted of erythema, vesiculation, and, in the worst places, profuse weeping and desquamation. Behind the ears a typical streptococcal intertrigo had supervened. Itching was severe. Its distribution was maximal on the face, the neck and shoulders where left uncovered by a singlet, the outer upper arms, the forearms, thighs, and legs. It was less marked on the chest and back, inner upper arms, and the feet. It was completely absent from the bathing-drawers area. At this stage the patient also showed an intense catarrhal stomatitis, glossitis, and pharyngitis, considerable prostration, and a fever of 102° for 10 days. The rash finally subsided in 2 weeks.

Discussion

Sulphanilamide was responsible for most of the milder cases (16 out of 17). The more severe cases were caused by sulphanilamide and sulphapyridine in equal numbers (5 of each). This greater incidence with sulphanilamide has been reported before, but in our cases it may have been due to the fact that only sulphanilamide patients were ambulant. In the largest series of cases in the literature at our disposal—that of Erskine (1939)—eruptions usually appeared at the eighth to tenth day, lasted 1 to 7 days, and were irritable in 20 out of 36 cases: although the majority of his cases were not described as light-sensitive, these features are in close agreement with our own observations.

Case 10 above merits separate discussion. It differs conspicuously from the remainder in its onset on the first day of chemotherapy, without sunlight exposure. Yet its distribution left no doubt as to its photosensitive character, affecting sites in order of their *previous* exposure to light. This early onset suggests an allergic origin. Epstein (1939) has described two types of photosensitivity from sulphonamides. Irradiating with ultra-violet light the site of an injection of sulphanilamide, he obtained an erythematous reaction. In the same subject 9 days later, irradiation of another injection site produced a more severe, prolonged, and exudative reaction, to which he gave the name "photo-allergy." Our own case was also atypical in its exudative nature.

Summary and Conclusions

In their power to cause an eruption in parts previously exposed to the sun sulphonamides resemble pellagra.

In all, 27 cases of light-sensitive sulphonamide eruption are described, 21 due to sulphanilamide and 6 to sulphapyridine. These represent 3.4% of the total cases treated with these drugs, under conditions favouring considerable exposure to constant strong sunlight. About half the cases occurred during July and August.

Photosensitivity occurs from the eighth to the tenth day of administration. Two cases were found to be photosensitive 2 days after stopping chemotherapy. It therefore appears that patients given sulphonamides for more than 6 days are possible victims of sunlight eruptions.

In many cases the presence of melanin is a protection against these eruptions. Three observations support this: (1) about one-third of the cases are subjects who sunburn easily; (2) the bronzed parts of the body tend to be affected less than the others; (3) no eruptions have ever been seen in Maoris, who comprised about 100 of the 800 cases treated during the 12 months.

The following parts are affected in order of severity: (*a*) parts exposed to the sun during chemotherapy; (*b*) parts exposed in the past; (*c*) pressure points, such as the great trochanters; (*d*) least of all, parts always kept covered, such as the bathing-drawers area.

The commonest lesions are erythematous papules in a morbilliform or roseoliform pattern, becoming confluent. Itching varies (severe in 5, moderate in 7, slight in 9, absent in 6). Less common lesions are oedema, urticaria, vesication, pustulation, and desquamation.

Drug fever and other toxic effects are common accompaniments (12 cases).

Most rashes subside in 2 to 4 days.

Further chemotherapy.—Avoiding exposure to sunlight, 6 cases completed their courses of chemotherapy and 3 had further courses later without ill effects. In the milder cases, at all events, a rash is no indication for discontinuing the drug.

CHRONIC LEG ULCER IN PURPURA HAEMORRHAGICA

REPORT OF TWO CASES

BY

L. J. WITTS, M.D., F.R.C.P.

Nuffield Professor of Medicine, University of Oxford

The association of chronic ulcer of the leg with splenomegaly seems too frequent to be a mere coincidence, though the reason for it is not known. It has been described in sickle-cell anaemia, acholuric jaundice, Gaucher's disease, splenic anaemia, and Algerian splenomegaly. Last December I had two patients with essential thrombocytopenia, both of whom had had chronic ulcers of the leg. Although I had previously seen patches of purpura break down and ulcerate in patients who were acutely ill, the occurrence of chronic ulceration of the legs was new to me. The spleen was not palpable in either of these two patients, but in view of the important part which the spleen plays in purpura haemorrhagica, the cases seem worth reporting as a further contribution to this odd chapter of medicine and surgery.

Case Reports

Case 1.—A woman aged 21 was admitted to hospital because of menorrhagia. She had had the trouble ever since her periods started at the age of 12. At 15 there appeared on the left leg an ulcer which was very indolent and did not heal for more than two years. During this time it gradually increased in size until it measured about 10 by 5 cm. When she was 17 a similar ulcer appeared on the right leg, but cleared in a shorter time. Neither had broken down since. On the lower third of both legs there were large thin paper-like scars. There was no surrounding discoloration, and the scars were not tender. As the patient had only 19,000 platelets per c.mm., splenectomy was advised, and a spleen weighing 284 g. was removed by Mr. Elliot-Smith. The patient made an excellent recovery. She was completely relieved of all symptoms, and seven months after operation her platelets numbered 338,000 per c.mm.

Case 2.—A man aged 26 was admitted to hospital because of excessive bleeding after incision of a boil. All his life he had been subject to excessive bruising and bleeding. He had had chronic ulceration of the legs for 8 to 10 years. This had been treated without success by elastoplast and other methods used for varicose ulceration, though there was no varicosity. His story was that the lesions began as a red patch in the skin, of small size, changing to a light chocolate colour and coalescing with other similar areas. The skin then became thin and papery and might ulcerate. Once the chocolate stage was reached it never returned to normal. When he was up and about his ankles became oedematous and his legs ached. He often had to give up work on this account. On examination there were numerous small brown patches on the lower parts of his legs and on his feet. On the inner side of the left heel there was a larger area which had ulcerated at the centre and was covered with a thick brown scab. In the middle and lower thirds of the anterior aspect of the right leg there was a saddle-shaped lesion about 15 cm. in length, which was chocolate-coloured and ulcerated in its lower part. There were no bruises or purpura elsewhere on the limbs or body. As his platelets were usually below 20,000 per c.mm. splenectomy was advised, and Mr. Elliot-Smith removed a spleen weighing 122 g. Unfortunately the operation was not followed by any significant rise in platelets and there was only temporary healing of the ulcer, attributable to the rest in bed. Six months after the operation, although the bleeding time had fallen from 15 minutes to 3 minutes, there were still only 54,000 platelets per c.mm. and the ulcer of the right leg had broken open again.

Three out of every four negroes with sickle-cell anaemia have chronic ulceration of the legs (Cummer and LaRocco, 1940). Unfortunately the early stages of the lesion have not been observed, and by the time the ulcers come under medical care they are described as punched-out chronic ulcers with a base of granulation tissue. They respond to symptomatic treatment, but are likely to relapse owing to the intractable nature of the underlying malady. In acholuric jaundice ulceration of the legs is a much less frequent complication, though at least 18 cases had been recorded by the beginning of 1939 (Taylor, 1939). The lesions, which are commonly near the internal malleolus, begin as a dusky-blue area which breaks down in the centre. A ring of bluish cyanosis or dark pigmentation circumscribes the lesion. Vaughan and Turnbull (1936) described ulcers with pigmented margins and scars with pigmented borders; microscopical preparation showed that the dermis for a considerable distance beyond the margin was densely infiltrated with plasma cells and contained numerous macrophages loaded with granules of iron, while its vessels were greatly engorged. The French authors who reported chronic ulceration of the legs in splenic anaemia (Grégoire and Emile-Weil, 1929) and Algerian splenomegaly (Lombard and Nanta, 1928) thought that the leg ulcer was primary and formed the portal of entry for bacterial or mycotic infection, but this idea is not in keeping with modern views of the pathology of splenomegaly. In the cases which I am reporting the lesion appeared to begin as an extravasation of red blood cells with subsequent ulceration over the purpuric area. It is very similar in appearance and pathology to the pigmentation of the legs in Gaucher's disease (Bloem, Groen, and Postma, 1936). It is clear that thrombocytopenia is not a common factor, for the platelets are normal in acholuric jaundice and sickle-cell anaemia. Nor is the ulceration explained by the anaemia, for chronic ulceration of the legs has not been described in pernicious anaemia or chlorosis. Mere size of the spleen is not significant, inasmuch as ulceration is absent in the gross splenomegaly of leukaemia and present with much less enlargement. Finally, there is no correlation with clubbing of the fingers, another peripheral abnormality which is curiously associated with splenomegaly. Both clubbing of the fingers and chronic ulceration of the legs are suggestive of vascular changes in the limbs, and in more leisured times it would seem appropriate to carry out careful studies of the peripheral circulation before and after operation in similar cases.

CHIP FRACTURES OF THE OS TRIQUETRUM (CARPAL CUNEIFORM)

BY

T. J. FAIRBANK, M.B., B.Ch., F.R.C.S.
Major, R.A.M.C.

Eleven fractures of the os triquetrum have been seen out of a total of 86 wrist injuries referred to a small fracture clinic during the last year. This gives a false impression of their relative frequency, in that all triquetral fractures were sent to this clinic while many other wrist injuries were treated elsewhere; nevertheless, they are much more common than was previously supposed. Greening (1942) has recently stressed this frequency, quoting 20 out of 580 wrist injuries seen at Charing Cross Hospital during two years. He has described how the bone may be crushed between the pisiform and the lower end of the ulna, classifying the fractures according to their *x*-ray appearances, and giving a full bibliography, to which unfortunately there is no access in this station. A study of the cases seen here agrees largely with his analysis, but has brought out certain differences which it is proposed to describe. Of the 11 fractures 10 were small chips or flakes about 3 mm. in diameter separated from the middle of the ulnar dorsal border; the eleventh was a complete fracture through the middle of the bone in the sagittal plane with no displacement. In no case was there any other associated bone injury.

Aetiology

All were due to a fall on the hand, one in volar flexion, the remainder in dorsiflexion. Six of the latter gave the following clear-cut history: Each patient said that he was walking downhill when his feet skidded forwards; he then fell backwards on to his outstretched hand, was unable to save himself, and finished up on his back. They were unable to remember in which direction their fingers were pointing, but it is suggested that they were pointing outwards to the side, that the first strain was one of dorsiflexion, immediately followed by forcible ulnar deviation as they rolled backwards over the ulnar border of the hand, and that this is the trauma *par excellence* that would crush the os triquetrum against the lower end of the ulna. All the patients were soldiers, their ages varying from 23 to 37. In this station the roads are steep and the asphalt often slippery, and boots with hobnails polished smooth take little grip. Although one-third of all the wrist injuries seen occurred in men of the Royal Navy there were no triquetral fractures among them, an immunity possibly due to the plain leather soles of Naval footwear.

Physical Signs and X-ray Appearances

The patients presented a stiff weak painful wrist with maximum pain, swelling, and tenderness over the dorsum of the os triquetrum. In only one was the fragment palpable. A combination of dorsiflexion and ulnar deviation was typically the most painful passive movement. Only two men had signs of a sprain of the ulnar collateral ligament; the history of their injuries and the *x*-ray appearances confirmed the presence of an avulsion fracture in each case.

At *x*-ray examination the chip fractures were best seen in the lateral and were invisible in the antero-posterior view. From the lateral it was not always easy to say whether the fragment had come from the dorsum of the os triquetrum or of the lunate ; the oblique view, which is most important, showed the site of fracture in every case. This point was specially studied in view of the high figure (59 out of 1,106) for avulsion fractures of the posterior process of the lunate in Schnek's series as quoted by Böhler (1935). In the lateral view they varied from a minute flake to an oval fragment 4 mm. in greatest diameter. In the two men with ulnar collateral ligament damage the fragment had been pulled proximally ; of the remainder it lay over its bed in 3 and had been pushed distally in 5. In no case were there any radiating cracks or fissures through the rest of the bone. The accompanying radiographs show the largest and the smallest fragments.

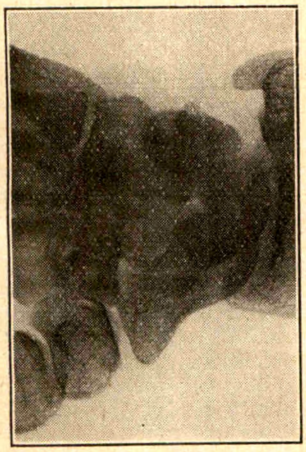

FIG. 1.—Pte. A.: Oblique view.

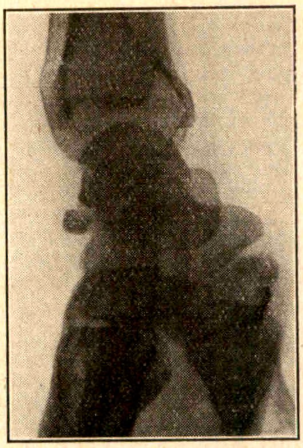

FIG. 2.—Pte. A.: Lateral view.

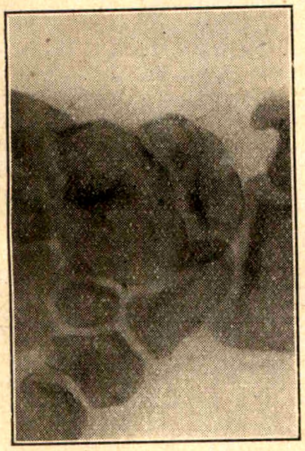

FIG. 3.—Pte. B.: Oblique view.

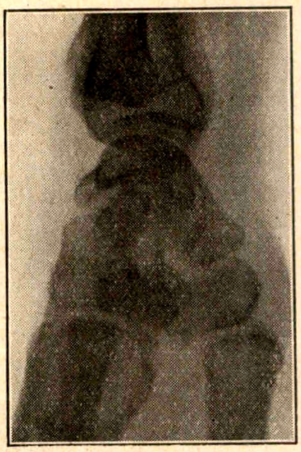

FIG. 4.—Pte. B.: Lateral view.

Treatment and Results

No attempt was made to reduce any displacement, which was never pronounced. The one complete fracture was immobilized in plaster-of-Paris for 15 weeks before union showed radiologically. The patient returned to full duty 4 weeks later. Eleven months after the injury the wrist was normal except for slight tenderness in the triquetral area.

The two avulsion fractures were also immobilized in plaster, one for 4 weeks, the other for 9 weeks ; these men were fit for all duties respectively 7 and 10 weeks from the injury. Nearly a year later they were both trouble-free, but one has limited flexion and very occasionally local pain ; in his case *x*-ray examination at 6 months showed union incomplete, but at 12 months union had taken place.

With the exception of one man with a severe sprain put in plaster recently and still under treatment, the remainder (7 cases) were treated with elastoplast strapping only, and were fit for full duty in 1 to 28 days, the average time being 10 days. They have been "followed up" for periods varying from 2 to 12 months. Of the 7, 4 are now normal in every way, one is normal except for slight limitation of flexion, and the other 2 suffer no inconvenience but still get slight pain on forced dorsiflexion. Radiographs show union to have taken place in all of them, although in some it was slow and still appears to be incomplete.

Conclusions

With such a small series it is impossible to draw wide conclusions, but the figures agree with those of Greening in showing that the fracture is more common than was formerly supposed. It is usually due to forcible dorsiflexion and ulnar deviation of the wrist, frequently the result of a backward fall on the outstretched hand. In *x*-ray diagnosis the oblique view shares importance with the lateral, and the chip of bone appears to be pushed off more often than pulled off. In the former the prognosis is excellent and recovery very rapid with minimal treatment ; although bony union may be delayed, immobilization does not appear to be necessary. The avulsion fractures, however, involving as they do damage to the ulnar collateral ligament, are more serious injuries and require longer treatment. It was a little surprising that the one complete fracture took so long to unite when immobilization was carefully maintained in a patient who had been using his hand to the full. Slight symptoms may persist for many months, but they do not interfere with the activities of the patient.

My thanks are due to Colonel J. R. N. Warburton, *M.C.*, A.M.S., and to Colonel W. A. Jackman, A.M.S., for permission to publish these cases, and to Major W. N. Brown, R.A.M.C., for his unfailing patience and excellent radiographs.

Medical Memoranda

Pneumococcal Meningitis successfully treated with Sulphapyridine

The following case, in which the chief features were the sudden onset and the rapidity of cure with sulphapyridine, is reported in order to draw attention to the possibility of lowering the mortality rate of pneumococcal meningitis.

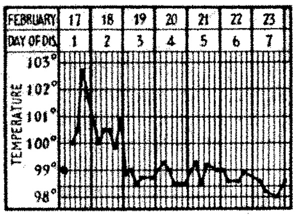
CASE REPORT

An unmarried woman aged 21 was admitted to hospital at 11 a.m. on Feb. 17, 1940. On Feb. 15 she had not felt very well, and on the 16th had sent for her doctor, who diagnosed influenza. Some spots were then present on her arms and legs and she also complained of diplopia. At 3 a.m. on the 17th she was very restless and started getting out of bed. She vomited 3 times, and by 5 a.m. was definitely unconscious.

On admission the patient was found to be comatose but very restless. Her head was retracted and her knees and hips flexed. She was lying on her side and giving out occasional meningeal cries. There were spots of an erythematous nature on her legs, and she was incontinent of urine and faeces. According to her mother she had not passed urine for 12 hours. It was difficult to examine her very thoroughly, as she was so restless, but there was definite evidence of squint and ptosis of both eyelids, the left being more marked than the right. Kernig's and Brudzinski's signs were positive, Babinski's sign was flexor, and the abdominal reflexes were absent. The only abnormal finding in her chest was evidence of slight consolidation at the left base. Her tongue was furred.

Under general anaesthesia 12 c.cm. of soluble sulphapyridine (equivalent to 4 g. of the drug) was injected intramuscularly. Lumbar puncture was performed, and turbid fluid ran out under considerable pressure, too high to measure with a manometer. A deposit soon settled at the bottom of the 40 c.cm. of cerebrospinal fluid that was taken, and from this deposit a slide was made which demonstrated extracellular pneumococci. There were 25,000 cells per c.mm., mostly polymorphs, with occasional red cells and macrophages ; protein, 0.5 g. % ; sugar, trace only ; chlorides, 725 mg. per 100 c.cm. Urine showed albumin +, sugar +, and acetone + ; its specific gravity was 1020. By 9 p.m. the patient was notably improved. Whereas previously she had been quite unconscious, she now recognized her doctor and was able to answer questions. A further injection of 12 c.cm. of soluble sulphapyridine was given and pot. brom. 30 gr. and chloral 15 gr. were administered by mouth.

Feb. 18.—The patient had passed a fair night, but was still very restless. She had drunk about 35 oz. of fluid since admission and had been incontinent of urine and faeces. She now knew where she was. Her colour, which had been pale and somewhat cyanosed, was improved. The pulse was good and the blood pressure 80/50. Kernig's sign was positive; Brudzinski's and Babinski's signs were negative. The head was still retracted, and there was still marked squint and ptosis. Slight papilloedema of both disks was noted. The white blood cells numbered 20,000 per c.mm.—76% polymorphs, 22% leucocytes. The urine was normal. Lumbar puncture was performed under general anaesthesia, 40 c.cm. of fluid being run out under pressure too high to read with a manometer. The fluid was considerably less turbid, and intracellular pneumococci were demonstrated. An injection of 6 c.cm. of soluble sulphapyridine was given intramuscularly in the morning and again in the evening.



Feb. 19.—The patient's condition was still improving. She had no headache, but complained of stiffness in her neck. She still rolled about a great deal in bed, and kept her knees well drawn up. Lumbar puncture was performed under general anaesthesia, 25 c.cm. of less turbid fluid being drawn off under pressure still too high to read with an ordinary glass manometer. 500 red cells and 500 white cells were found per c.mm.; protein, 0.08 g. %; chlorides, 760 mg. per 100 c.cm.; sugar, positive; Nonne-Apelt reaction, slightly positive. 6 c.cm. of soluble sulphapyridine was administered intramuscularly in the morning and again in the evening. Altogether 48 c.cm. of the soluble substance was administered in 3 days. The fall in temperature over this period can be seen from the Chart.

Feb. 20.—Lumbar puncture was performed under local anaesthesia and the fluid ran out at the rate of about 1 drop in 3 seconds, now being clear. The general condition of the patient was much improved, but Kernig's sign, head retraction, and ptosis of both eyelids, as well as diplopia, were still present. The squint was less marked. During the 24 hours 2 g. of sulphapyridine was administered by mouth.

Feb. 21.—The findings were similar to those of the previous day, but lumbar puncture was not performed. The blood pressure was 120/70. 2 g. of sulphapyridine was given by mouth.

Feb. 22.—A blood count showed 6,400 leucocytes per c.mm. There was no head retraction, Kernig's sign was negative, and slight ptosis and slight "blurring" of vision were still present.

Feb. 23.—Sight quite normal. No ptosis. Felt quite well.

May 1, 1942.—It has been ascertained by one of us (E. W. M. W.) that this patient has remained quite well; there have been no sequelae, and it is interesting to note that she is now serving with the Forces.

We wish to thank Dr. C. M. Hinds Howell for his kind advice throughout this case.

E. W. MEURIG WILLIAMS, M.B., B.Ch., B.Sc.,
Member of Hon. Medical Staff.
ELLIOT PHILIPP, M.R.C.S., L.R.C.P.,
Late House-surgeon.
Harrow and Wealdstone Hospital.

In a bronchoscopic investigation of asthmatic children E. L. van Loon and S. Diamond (*Amer. J. Dis. Child.*, 1942, **63**, 217) found no support for the theory of a bronchospastic origin of the wheezing and dyspnoea. Admitting that the bronchoscopist cannot explore the small peripheral bronchi and bronchioles, they agree with Jackson that spasmodic contraction of such small bronchi is hardly compatible with the production of a wheeze audible at the open mouth. In 100 asthmatic children non-specific inflammatory changes were observed in 91, and in 20 in whom bronchography was done 5 were found to have bronchiectasis. The only constant feature found in children examined during an attack was the presence of a thick viscid secretion within the bronchial lumen.

Reviews

PULMONARY TUBERCULOSIS

Pulmonary Tuberculosis and its Treatment. By Hans Jacob Ustvedt, M.D. Translated by A. L. Jacobs, M.R.C.P. With a foreword by W. D. W. Brooks, D.M., F.R.C.P. (Pp. 252. 25s.) London: John Bale Medical Publications, Ltd. 1942.

Dr. H. J. Ustvedt has written an extremely interesting volume on pulmonary tuberculosis, and, especially on the side of treatment, has gathered together a great many facts and observations which are well placed in the making of a readable book. He has evidently studied tuberculosis with a critical eye to the types prevalent at different ages and to the varying modes in which the disease tends to express itself in persons of means on the one hand and those subjected to want on the other. He is also prepared to see in immunity and resistance two of the principal factors on which the defence of the body depends. "In tuberculosis," he says, "as with other infections, *immunity* is the specific increase in resisting power which the organism acquires as a result of the infection. . . . *Resistance* is that power of withstanding the attack of the tubercle bacillus which the organism possesses apart from the effects of the infection itself." This distinction has long been made in England, though what Ustvedt calls "resistance" is usually spoken of as "natural immunity." He quotes the findings of Heimbeck and of Scheel, already familiar to tuberculosis specialists in this country, on the B.C.G. vaccination of tuberculin-negative probationer nurses at Ullevaal, by which they were brought up to the same level as the originally positive group—a finding which strongly suggests to him "that it is not only resistance but also immunity which is responsible for the low morbidity among the positive reactors." He notes, too, the marked effect of environment on the continued latency or the progressive development of the disease, citing malnutrition, poverty, occasionally pregnancy, strain, and other human trials as calculated to lead up the implanted infection to the clinical level.

Speaking of silicosis and the inhalation of dust, he remarks that "if we are to show a causative relation between a single factor associated with a particular occupation and the incidence of tuberculosis, all the other factors enumerated above"—here he means the environmental factors which we have mentioned—"must be taken into account. If this is done it becomes doubtful how far silicosis in itself really predisposes towards the development of tuberculous changes." We can only suppose that the author's acquaintance with silicosis is based on a much smaller experience than his knowledge of tuberculosis. As to the symptomatology of phthisis, his remarks are exceedingly valuable and should be read with interest and profit by all students of the disease. There is a good description of tuberculous meningitis—though it is assumed that this is nearly always connected with an attack of miliary tuberculosis—and there is no mention of tuberculoma of the brain. The author might well acquaint himself with the work of Arnold Rice Rich of the Johns Hopkins Hospital and of others on this subject.

In the book under review the question of treatment practically resolves itself into a consideration of collapse therapy. This concentration on what is perhaps the only type of treatment that counts at present is right and proper in a book intended to be a modern expression of the tuberculosis problem. The author very correctly condemns "high-pressure pneumothorax treatment," but we cannot agree with him that "the immobilization of the lung is almost entirely illusory" and that "the effect of treatment is at all events not related to this factor." Nobody believes that the lung is completely immobilized, but it is *relatively* immobilized by the cushion of air which prevents the constant drag of the expanding and contracting thoracic wall, and this must go far to explain the good results of pneumothorax therapy. We quite agree with him that this treatment really amounts to "a mechanical treatment of cavitation"; in fact, we are of the opinion that nearly every secondary tuberculous affection of the lung is accompanied by cavity formation, whether the cavities show in the radiograph or not. Ustvedt believes in bilateral pneumothorax, and devotes a considerable amount of space to this excellent measure. It is a curious side-light on his limitation to the Scandinavian and German literature that he fails even to mention the name of Parry Morgan, the distinguished Welshman who first introduced bilateral pneumothorax to the profession.

The author records his impression that "there are hardly sufficient grounds for the belief that superinfection is to any great extent responsible for tuberculosis morbidity," and expresses the opinion that "as for massive infection it appears that under existing conditions we are justified in disregarding this theoretical consideration." On these issues we might well join battle with him, for we regard both types of infection as extremely important. But we must not part from Dr. Ustvedt on a controversial note. We have read his book from cover to cover with the greatest pleasure and we commend it to all British tuberculosis officers and general practitioners. A tribute should also be paid to the excellent rendering of it into English by Dr. A. L. Jacobs.

THE AUTONOMIC NERVOUS SYSTEM

The Autonomic Nervous System. By James C. White, M D., and Reginald H Smithwick, M.D Second edition. (Pp. 46 35s) London: Henry Kimpton. 1942

The reputation of the Peripheral Vascular and Cardiac Clinics of the Massachusetts General Hospital is splendidly upheld by the second edition of White and Smithwick's book on the autonomic nervous system, for although they give a comprehensive survey of the contributions made by anatomists, physiologists, and clinicians working elsewhere, the book is surely founded upon their own extensive experience. Judicious pruning of the first edition has enabled the authors to add an enormous amount of new material in only eighty more pages; every chapter has been thoroughly revised, those dealing with physiology and pharmacology as well as the later ones on the clinical and surgical aspects of the disorders of the anatomic system. The authors have wisely stuck to the plan of placing the description of surgical technique in a separate section of the book, for although there have been striking changes in this field during the past seven years, the rest of the volume shows how greatly experience and experiment have altered the approach to many of the problems of the autonomic system—matters of interest not to surgeons alone but to all clinicians. The work proceeds, and there are still many gaps to be filled, but we welcome this volume as the most authoritative book on the subject at the present time.

AMPUTATIONS AND ARTIFICIAL LIMBS

Amputations and Artificial Limbs By R D. Langdale-Kelham, M.R C S., L R.C P., and George Perkins, F R.C S. (Pp. 96. 5s. net.) London: Oxford University Press. 1942.

Here in the neat form of the *Oxford War Manuals* is all that the student and surgeon need know about amputations at the present time. The experience of the authors at the Ministry of Pensions Hospital at Roehampton is a guarantee of the sufficiency of the information.

The strictly surgical aspect of the problem is considered in 47 pages. Such conciseness is only possible by virtue of the excision of all dead and dying wood. A sentence from the preface shows to what extent this has been achieved: "Chopart, Stokes-Gritti, Carden, Smith, Pirogoff, Furneaux-Jordan, Farabœuf, Lisfranc, Syme—must they all go? We are afraid so, even Syme." That the desirable amputations in the lower extremity could be brought within the bounds of three main types has been generally accepted for some time, and this book systematizes the subject on these lines.

The authors define the seat of election for below-knee amputations as 5½ inches below knee level. For above-knee sections they advise that 10 to 12 inches of femur should be left, measuring from the great trochanter. Their advice on the cutting of flaps and the detailed technique of the operation is worth careful study. Their advice as to when to amputate is brief and to the point, though some surgeons would consider that they tend to an undue conservatism, at any rate in relation to severe injuries in the lower half of the leg. The chapter on the post-operative treatment of stumps is of great value and contains many useful practical hints; the sections on teaching the patient to use an artificial leg or arm, respectively, are particularly interesting. The latter half of the book is devoted to mechanical or engineering details of the artificial limbs in current use. Much of this information made available from the authors' extensive store will be new to many surgeons.

This brisk and confident volume can be recommended to the student; but it is to the surgeon who hitherto has had little practical experience of the subject that it will prove an invaluable source of sound advice.

ORBITAL TUMOURS

Orbital Tumors: Results Following the Transcranial Operative Attack By Walter E. Dandy. (Pp 168 25s) London: H. K Lewis 1942.

Tumours of the orbit present considerable difficulties in diagnosis and treatment, and when examined histologically a proportion of such tumours prove to be inflammatory masses—the so-called pseudo-tumours of the orbit. Small masses situated anteriorly in the orbit are fairly easily removed by an incision through the conjunctiva or the lid, but deeply situated tumours have taxed the ingenuity of both ophthalmologists and general surgeons. The classical Krönlein operation was devised to allow access to the deeply situated tumours, and the large number of modifications that this operation has undergone provides a doubtful testimony to its efficacy. Moreover, when a deeply situated tumour is exposed by the Krönlein operation, or some modification of it, complete extirpation of a neoplastic mass is more often assumed than seen. Clearly this is an unsatisfactory state of affairs, particularly in the light of pathological investigations, which have shown that many orbital tumours are orbital extensions of intracranial growths. It was only by slow degrees that the obvious procedure of an intracranial approach to the orbit allowing inspection of both intracranial and orbital contents was evolved.

Dr. Dandy in this valuable monograph tells of how at one intracranial operation he was forced to open the orbit and of his fears that a pulsating exophthalmos would inevitably follow. The almost trivial incident through which intracranial exposure of the orbit came to be elaborated is but an illustration that in the hands of a master a difficulty becomes the key to a solution. Ophthalmologists and neurosurgeons alike owe to Dr. Dandy an operative procedure which is giving increasingly satisfactory results in competent hands. The present monograph is largely a record of twenty-five cases studied at operation, together with seven additional non-operative cases. This group, probably the largest that any individual surgeon has dealt with, reflects the difficulties in pathological classification, no fewer than fourteen different conditions being met with; only 20% of the cases were confined solely to the orbit. Malignancy of some degree or other was present in most cases; in only three of them could one be sure of a permanent cure. The operative approach is similar to that for the pituitary: the roof of the orbit is removed after evacuating the cisterna chiasmatis; retraction of the frontal lobe then provides sufficient room. A considerable simplification of the operation has come about through the introduction of avertin. With avertin anaesthesia the brain does not swell as it does with ether, and a smaller flap can be planned.

Notes on Books

Expectant Motherhood, by Prof. NICHOLSON J. EASTMAN of Johns Hopkins University, is published in this country by John Murray (price 6s.). "If you are going to have a baby you will want this book," according to the advice given on the attractive loose cover in which this little volume is dressed Possibly few of our readers will qualify for a copy on this basis alone, but all who are engaged in obstetrical work will be interested in Prof. Eastman's compilation. It is written in the hope of dispelling that widespread ignorance which causes so much fear, anxiety, and at times needless suffering to pregnant women and women in labour. For this reason it is written simply and with a sympathetic kindliness that cannot fail to appeal to its readers. Much more information is given than one woman will need to know on subjects ranging from the symptoms and signs of pregnancy to the care of the unborn babe. Controversial matters such as anaesthesia and analgesia in labour are wisely and fairly handled in such a way that both sides of the problem are presented to the patient while still leaving freedom of choice and action to the doctor she has engaged. This is a book which could be recommended with confidence to expectant mothers.

THE SULPHONAMIDES IN OPHTHALMOLOGY

Though the interior of the eye is prone to a variety of inflammatory reactions, microbial infection is not common, and when it occurs it generally leads to rapidly destructive panophthalmitis. The sulphonamides, with their largely selective actions on the streptococcus, pneumococcus, meningococcus, and gonococcus, would not, therefore, appear to be promising in combating anything beyond the microbial infections of this type seen in the conjunctiva. Actually, the clinical use of the sulphonamides in ophthalmology has been both unexpectedly successful and disappointing. The most striking results are seen in ophthalmia neonatorum. Here sulphanilamide itself proved rather erratic, and more was hoped from sulphapyridine with its greater selectivity for the gonococcus, the causal organism in some 30% of cases. In practice sulphapyridine proved remarkably effective in all types of ophthalmia neonatorum, in the staphylococcal no less than in the gonococcal type[1] or in inclusion blennorrhoea.[2] The results in ophthalmia neonatorum are so uniformly good that bacteriological examination to establish the identity of the causal organism is almost superfluous; in all cases a clinical cure may now be expected in as many days as weeks were formerly needed. With appropriate treatment, as recently recorded in these columns,[1] ophthalmia neonatorum should cease to carry dangers to sight from corneal complications. Equally gratifying results are obtained in purulent conjunctivitis in older children and adults; this is clearly the case in gonococcal and meningococcal infections, but is less fully established for staphylococcal infection. Hypopyon keratitis, generally caused by the pneumococcus, often responds well to treatment, but failures are not uncommon. In trachoma, early reports[3] raised hopes of a quick cure of this stubborn infection, a hope supported by the efficacy of the sulphonamides against the allied virus of lymphogranuloma inguinale, but it would appear that the sulphonamides are merely a valuable adjuvant to the classical methods of treatment, acting, perhaps, only by their effect on the secondary infection which is almost always present.

Isolated case reports have been published on the value of the sulphonamides in a variety of severe intra-ocular infections, including sympathetic ophthalmia and panophthalmitis.[4] There is more convincing evidence of their efficacy in post-operative inflammation and in infections seen in perforating injury of the globe with retained foreign bodies.[5] Good results are seen in many cases of acute iritis and iridocyclitis, though unfortunately this is not the rule, while in chronic iridocyclitis and uveitis, even when presumably due to the gonococcus,[6] the results are disappointing. Good results are also reported in herpes of the cornea.[7] In orbital infection and dacryocystitis the sulphonamides are valuable but do not lessen the need for evacuating pus where this has formed. There is an isolated case on record of recovery from orbital cellulitis complicated by meningitis.[8] Remarkably few ocular complications have been recorded from the widespread use of sulphonamides. An early report[9] suggested the danger of optic neuritis, but a transitory myopia appears to be the one frequent complication encountered.[10]

Experimental studies have been more concerned with assessing the level of concentration that the various sulphonamides reach in the ocular tissues than with the efficacy of these drugs in different experimental infections. There is substantial evidence that they are effective in streptococcal infection,[11] and possibly in infection due to the Koch-Weeks bacillus (*H. influenzae*).[12] Some work has also been done on *B. pyocyaneus* infection, but the evidence is conflicting.[13] Corneal lesions produced by intracorneal inoculation with staphylococcus appear to be favourably influenced by the local application of a soluble sulphanilamide.[14] The work dealing with levels of concentration of the sulphonamides in the eye has followed two distinct lines—one concerned with assessment of the relative value of the various sulphonamides in reaching the eye and maintaining high levels of concentration, and the other aiming at a similar evaluation of the various methods of local administration. There is probably little difference in the aqueous level of sulphanilamide and sulphapyridine. Sulphadiazine reaches high aqueous levels (about 75% of the blood level) after an initial lag, but sulphathiazole attains distinctly low concentration in the eye, somewhere around 20% of the blood level.[15] This would imply that the value of sulphathiazole in ophthalmology is limited, and there are no clinical data to contradict this; in ophthalmia neonatorum it has been found less effective than sulphapyridine.[16] As for the relative value of the various methods of local application, ointments are more effective in giving and maintaining high levels than solutions.[17] The complexity of the molecule of the particular drug used is also of significance: a complex sulphonamide, like prontosil soluble, fails to be absorbed into the aqueous when injected subconjunctivally.[18] A suitable sulphonamide, such as sodium sulphacetamide ("albucid"), gives high levels in ocular tissues when introduced in fluid form into the conjunctival sac,[19] but it is likely that under clinical conditions application in ointment form is the better method. The values that have been reached with local application of sulphonamides are distinctly higher than those that can be safely reached by oral administration. In man aqueous concentration of 20.7 mg. per 100 c.cm. has been obtained by the insufflation of sulphanilamide powder into the conjunctival sac[18]—a value about three times that obtainable by oral administration; in animals concentrations many times higher than this are easily obtained.

If concentration were the only factor in assessing the efficacy of a particular sulphonamide or of a particular method of administration, it is clear that local therapy with soluble sulphonamides would be the method of choice.

Both clinical and experimental evidence seem at the present to indicate that oral administration, in spite of its lower levels of concentration in the ocular tissues, gives much more satisfactory results, but that the problem is still undecided is obvious from the somewhat contradictory results reported at the last annual congress of the Ophthalmological Society.

THE SHAPE OF A SMELL

Too often physiology and medicine are linked only in the memory of the practitioner. In wartime particularly a disorganized practice, the filling up of forms, a call to the colours, in addition to preoccupations with social problems and financial perplexities, distract the doctor from the foundation of his training, and advances in the true science of medicine become for him faint echoes from a remote campaign. Progress in the more specialized technical fields is especially hard to follow, as the communiqués are usually spiced with new jargon and are often reserved to the point of inscrutability. Our attention is attracted, however, by the two extremes—the bizarre and the practical—examples of which are to be found in publications on electrophysiology, once patronizingly called the prodigal son of biology, now a fast-growing aid to neurologists.

One of the earliest and simplest uses of electrophysiological methods was in the study of the special senses. An animal cannot describe its sensations, and to take the place of subjective reports methods have been devised to record from the nerves and brain the stream of nerve impulses set up when a receptor is stimulated. In this way the anatomical distribution of sensory tracts has been physiologically plotted, and, what is more, the means whereby differences in strength and quality of stimuli are conveyed to the brain have been analysed. It seems that differences in strength and intensity are transmitted from receptor to brain as variations in the frequency of impulses, each one of which is always the same size. Variations in quality are perceived by selective sensitivity of different end-organs. This rule is known to apply to the simpler end-organs of skin and muscle, but whether it holds true for the ear, eye, and nose is not so certain. The sense of smell particularly has puzzled both physiologists and psychologists, for no clear physical basis is known for the elusive and private world of odour.

In human affairs smell has degenerated into an aesthetic side-show, a pivot for a luxury trade, and it is only recently that the ability to distinguish between musty hay, geraniums, and garlic has regained its status as a factor in survival. So ancient in evolution is olfaction that in most mammals its nervous centres have been overlaid with a more recent acquisition, the neopallium, so that the olfactory nerve and cortex are relatively inaccessible to the physiologist's electrodes. This obstacle has been surmounted by Prof. E. D. Adrian, O.M.,[1] who has pressed into service the common hedgehog, because its simple and unambitious brain leaves exposed a part of the pyriform cortex and the olfactory bulb. When the animal was lightly anaesthetized normal breathing produced a regular series of large potential waves in the pyriform area at each inspiration. These waves were the result of mechanical stimulation by the air of the olfactory epithelium. Their frequency could be raised by forcibly blowing air through the nose. When a distinct odour, say of cloves or asafoetida, was added to the air, these regular waves vanished and their place was taken by small irregular waves. A very strong smell evoked a continuous discharge at a higher frequency. In Adrian's experiments the most potent stimuli were the smell of decaying worms and cigarette smoke.

The significant difference between the results of mechanical and olfactory stimulation is that the former has a uniform effect giving large synchronous waves in the cortex, whereas the latter is not uniform and has a more selective action on different parts of the receptor mechanism. Adrian suggests that "different chemical stimuli produce different distributions of excitation, and that a familiar smell, like a familiar sight, is recognized by the specific pattern which it arouses in the brain." If borne out by further experiment this hypothesis would bring the sense of smell into line with other senses, both in the peripheral mechanism whereby chemical changes are converted into nervous impulses, and in the central nervous processes, in which synchronized electrical activity is associated with physiological rest or passivity. Even if we cannot yet talk of the shape of a smell we may perhaps look forward to the adoption of the "standard hedgehog" for biological perfume assay and the calibration of rival brands of cigarette. Apart from this slightly frivolous speculation there are several features of the sense of smell which may be explored by Adrian's method. It would be interesting to know whether the remarkable degree to which adaptation may occur in olfactory sensation depends upon a peripheral or a central mechanism. The neutralization of one smell by another seems little understood although it is in daily use.

The generalization that a stimulus capable of arousing a discriminatory response also suppresses synchronous electrical activity in the central nervous system is met with again in the application of electrophysiology to neurological problems—electro-encephalography. The normal resting electro-encephalogram consists almost entirely of the synchronous electrical rhythm from the visual integrative areas, the so-called alpha rhythm. This rhythm, as Adrian was the first to prove, tends to disappear when the eyes or mind are engaged in discriminatory activity, and the human cortex behaves in this respect like the primitive olfactory centres of the hedgehog. But synchronous rhythms are not the exclusive property of resting normal neurones. Abnormal conditions evoke slower rhythms, and these can be located in cases of cerebral tumour, brain injury, and so forth. The difficulty in interpreting abnormal electro-encephalograms is to be sure of the extent of normal variation, and much tedious work must be done to establish this. In a survey of 900 subjects Williams[2] found that in flying personnel of the R.A.F. only 5% showed anything which could conceivably be called abnormal, whereas twice as many were found in a group of non-combatants of other services; five times as many in a series of psychoneurotics. Judged by the same criteria, 60% of all epileptics were abnormal—a figure confirming the early results of other workers in this country.

There can be no doubt that the electrical behaviour of the brain reflects in a very precise way the constitution and potentialities of the nervous system, apart from the presence of gross pathological changes. The detail of the picture still depends upon the refinement of method and the experience and patience of the observer, but a powerful tool is available to all interested in human problems, from the philosopher to the recruiting board. If the hedgehog symbolizes for us the idea of defensive lethargy and the fighting airmen the very reverse, we can be satisfied that the qualities we most admire, whether in peace or war, are reflected by impersonal instruments as an image of vigorous individual activity, even in the minute and innumerable units of the brain.

DR. A. G. NICHOLLS AND THE C.M.A.J.

Dr. Albert George Nicholls, F.R.S.C., F.R.C.P.C., has retired on grounds of health from the post of Editor of the *Canadian Medical Association Journal* and is succeeded by Dr. H. E. MacDermot. Dr. Nicholls was born at Shotley Bridge, Co. Durham, and had a most distinguished career at Montreal High School and at McGill University, and after graduating in arts and medicine was a member of the teaching staff of his university for seventeen years. He then became professor of pathology at Dalhousie University and director of the Public Health Laboratories at Halifax, N.S., and during the last war he was D.A.D.M.S. Sanitation with the rank of Major C.A.M.C. Dr. Nicholls is the author of some 50 monographs and other publications on medical subjects, and succeeded the veteran Dr. A. D. Blackader as Editor of the *C.M.A.J.* in 1929. Under his editorship our contemporary has done fine work for Canadian medicine, and he has upheld the tradition of cordial good will towards the British Medical Association and the *B.M.J.* A man of wide interests and culture and an accomplished writer and journalist, his friendship is valued by many colleagues in this country. The Canadian Medical Association has appointed Dr. Nicholls Consulting Editor so that he may retain an active interest in the *C.M.A.J.*, and has paid him the high compliment of election to Honorary Membership. According to its constitution there can never be more than 25 Honorary Members at any one time.

OXYGEN POISONING

The work of Paul Bert,[1] Lorrain Smith,[2] and others has established that for very prolonged treatment by inhalation of oxygen the gas should not be given at a higher concentration than 60% of one atmosphere. Though a great deal of recent research has been carried out on this point in connexion with the use of oxygen by aviators and its administration to patients with anoxia, nothing has occurred to alter the above general rule. The only difficulty has been to determine for how long the pure gas—that is, at 100% of one atmosphere—may be breathed without danger to human life. As J. H. Evans and C. J. Durshordwe[3] and others have shown, some patients can tolerate the pure gas for limited periods with great benefit to their condition. It is becoming apparent that the reactions of different subjects to the pure gas vary widely. As oxygen will diffuse less rapidly through a surface covered with an increased amount of fluid, pure oxygen is required in such cases so that enough oxygen may reach the blood. Some authorities have advocated that pure oxygen should not be breathed for longer than 48 hours, and, after that, the concentration should be lowered to 60%. It is also advised that pure oxygen should be given for continuous periods of not more than five hours at a time, with intervals at the lower and safe pressures.

Lorrain Smith found that prolonged breathing of oxygen at a higher percentage than about 70 caused congestion and consolidation of the lung in normal animals, and this seemed to establish that the lungs were the main site of the trouble. He used mice and small birds chiefly, but also some rats, guinea-pigs, and pigeons. Some animals were more sensitive than others, and the percentage of oxygen required to inflict the damage varied with the resistance of the individual. Most of the later researches give similar findings, but some observers report that death may occur without definite consolidation of the lung. Thus Argyll Campbell[4] found that cats were adversely affected when subjected for prolonged periods to only 60% of an atmosphere of oxygen; they lost appetite, became much weakened, and lost weight rapidly, with a fall of metabolism and body temperature before death. There was general wasting of tissue with collapse and congestion of some of the alveoli of the lung and the presence of a few catarrhal cells, without any sign really typical of pneumonia. He suggested that some poison was formed in the lung by the action of oxygen at high pressure upon the epithelium. His rabbits, monkeys, and guinea-pigs, like most animals, could tolerate oxygen at 60% without harm. Recently J. R. Paine and his colleagues[5] observed that dogs could not tolerate prolonged respiration of oxygen at over 75% of an atmosphere, and exhibited lethargy, anorexia, and dyspnoea. The pathological changes they report are congestion and hyperaemia of the lungs, liver, and kidney, pulmonary oedema, and pleural effusion. They suggest, as did K. Retzlaff,[6] that death might be due to constriction of pulmonary blood vessels with some derangement of vascular physiology, although there is also obvious irritation of the respiratory epithelium. They give the literature in which evidence was obtained that oxygen constricts the blood vessels of the retina and of the brain. However, this constriction of the retinal vessels does not always occur, as Argyll Campbell and Leonard Hill[7] report that Duke-Elder could not detect such constriction in their subject after breathing pure oxygen for five minutes. Other factors that influence oxygen poisoning, at all events at pressures higher than one atmosphere, are external temperature, carbon dioxide pressure, and starvation. A. Almeida[8] found that starvation promoted resistance to oxygen poisoning, and this was confirmed by Campbell,[9] who observed that a rise of external temperature to 33° C. increases sensitivity to oxygen poisoning. He found also that thyroidectomy has a protective influence[10] and that inhalation of oxygen at high pressure, even at 60%, increases the carbon dioxide tension in the tissues. Leonard Hill[11] demonstrated that when animals breathe carbon dioxide at 5% of an atmosphere they become less resistant to oxygen poisoning. R. Gesell[12] and others have suggested that under increased oxygen pressure, with the haemoglobin fully saturated with oxygen, the blood cannot remove carbon dioxide from the tissues, and this is a factor in oxygen poisoning. However, the problem is still far from complete elucidation.

J. R. Paine and his colleagues, from their results with dogs, agree that the administration of pure oxygen must be intermittent and also report on another aspect of the subject. They confirm the previous finding of others that oxygen inhaled at 95–100% of an atmosphere tends to remove the gases—nitrogen, etc.—from the obstructed intestine. They give some analysis of the enclosed gas which seems to indicate that, during the breathing of oxygen, the pressure of carbon dioxide in the free gas may fall temporarily to a very low level—namely, 0.4%. This is a surprising result, for we can find no other evidence that the CO_2 pressure within the body or lumen of the gut falls below that of the arterial blood, which is normally about 5% and tends to increase while breathing oxygen both in man and animals. Also even in pure nitrogen or air freshly injected into the stomach or elsewhere the pressure of CO_2 in the injected gas rapidly rises to that of the arterial blood and then exceeds it. Campbell[13] reviews the literature to 1931, and recent researches confirm the main conclusions therein. He[14] tried to remove the carbon dioxide from the body of an anaesthetized cat by vigorous and rapid mechanical inflation and deflation of the lungs with air; after more than two hours of this pumping CO_2 was still present in the arterial blood at a pressure of almost 1% of an atmosphere and at a higher pressure still in the tissues. Hence the low figures obtained by Paine and his colleagues need confirmation. The needle and syringe method of withdrawing samples of gas from the intestine and other cavities holding their normal contents is liable to error unless the withdrawal of the gas is carried out with the tissue and syringe under fluid to shut off external air. It is also advisable for confirmation to analyse a volume of 10 c.cm. of gas in a Haldane precision apparatus rather than a bubble in a micro-apparatus. If low results for carbon dioxide obtained by Paine and his colleagues are confirmed, it is probable that some local fixation of that gas occurs in the intestine during breathing of pure oxygen. The after-effects of the double operation on the dogs to obstruct the gut may also be exerting some local influence. In any case, if supported, the results confirm that among other processes the CO_2-controlling mechanisms are deranged by inhalation of pure oxygen, as several others have noted.

CHAIR OF CHILD HEALTH AT NEWCASTLE

The University of Durham has gratefully accepted an offer from the Nuffield Provincial Hospitals Trust to provide a grant of £15,000 towards the cost of establishing a Chair of Child Health at King's College, Newcastle-upon-Tyne. The Senate and Court have appointed Dr. J. C. Spence as Professor, and the Council of King's College will provide him with the assistance necessary to the creation of a full teaching and research department. The Royal Victoria Infirmary, Newcastle, and the Babies' Hospital in that city, will co-operate with King's College by giving all possible facilities for the new department, which will be concerned with the preservation and restoration of the health of children. The Department of Child Health will provide undergraduate and postgraduate teaching in child health and the diseases of childhood; it will be a centre of research in those subjects, and will be at the disposal of local public health and education authorities of the region, for advice and consultation in the conduct of their child welfare and school medical services.

PAPWORTH'S PROGRESS

Paper shortage and "austerity" are responsible for the miniature report on the Papworth Village Settlement for 1941, but the facts recorded in it show that the settlement, in spite of the lamented death of its founder, Sir Pendrill Varrier-Jones, has fully maintained its rate of growth and expansion. Papworth has well-equipped hospitals, sanatorium units, and hostel units, and all these, with various annexes, cottages, and workshops, form an administrative whole—the Village Settlement. The surgical unit (the Nelson-Langermann Hospital) has a good record of work, and an attempt is being made to follow up all thoracoplasties done since its inception in 1936. The out-patient department deals with casualties and minor ailments among the patients and the village population, and also controls the clinics devoted to ante-natal and child welfare, physiotherapy, collapse therapy, and refractions. Sixty-six artificial pneumothorax inductions were made and 1,900 refills given during the year under review. The health of the village was excellent. Six healthy children were born. All children of school age and those from 3 to 5 years were examined by *x* rays, the results confirming the absence of any signs of active tuberculosis. The department of radiology does a large volume of work. Since 1933 over 13,000 radiographs have been taken and more than 18,000 screen examinations made. There is much activity in the research department, the pathological department, and the industrial physiology laboratory. The *Research Bulletins* recently reviewed in these columns record the results of investigations completed from time to time. The industries comprise wood, leather, fabric, and printing: the work has been adapted to wartime conditions. General Sir Reginald Wingate has been appointed chairman; the new vice-presidents are Lady Willingdon, Field-Marshal Lord Birdwood, and Sir Arthur MacNalty.

INFORMATION OR PROPAGANDA?

Last week we printed a full summary of the Shakespeare Committee's reports on economy of medical man-power published by the Ministry of Health on Sept. 3, and also reviewed the implications of these reports in a leading article. On the same day on which the *Journal* appeared—in the Home Counties at least—an account was given in the daily papers of a press conference held at the Ministry of Health on Sept. 3, and publicity to this was also given over the air. We much regret that the official information made available to us for transmission to those primarily concerned—namely, the doctors of this country—was not as complete and as informative as that which the Minister of Health saw fit to give to a press conference which the medical press was not invited to attend. Whatever may be the motives and reasons of the Government Department concerned in taking the general public more fully into its confidence than the medical profession itself—at least in so far as its chief organs of opinion are concerned—we cannot escape the conclusion that such lack of co-operation makes it less easy to preserve harmonious relations between the Ministry of Health and the doctors who actually carry on the work of caring for the health of the people. And this is just one incident among others. A recent letter in these columns from one who signed himself "Deputy Medical Officer of Health" drew attention to the fact that the "brochure" on diphtheria immunization issued from the Public Relations Department of the Ministry ignored the potential services of the general practitioner in the diphtheria immunization campaign now being prosecuted. At another press conference recently held at the Ministry the journalists assembled were told of the satisfactory state of nutrition existing in the population at large, and the Ministry of Health associated itself with the Ministry of Food in claiming the credit for this, but made no reference at all to the part played by the practising doctor, whose close daily contact with the men and women of the country makes it possible for them to partake of the benefits of modern medical science.

The facts given to the press conference—which we have had only at second-hand, being obliged to take them from press cuttings—are that, in attempting to solve the very difficult problem of allocating medical man-power, 800 alien doctors have been taken into employment, that since the outbreak of war well over 10,000 medical men have joined the Forces, that out of a pre-war total of nearly 19,000 general practitioners in England and Wales alone more than 4,500 have gone into war service, and that as a net result of this there is now one general practitioner for over 2,700 of the population. By scrupulously restricting our comment to the information given in the published reports we were able to tell the profession only "half the story." It is difficult to understand why the Ministry of Health disclosed part of the information in a published document and another part—perhaps the most telling part—to a lay press conference. We repeat the question in the title of this annotation.

War Medicine Series

The paper printed below is based on a lecture which was one of a series recently given at the British Postgraduate Medical School, Hammersmith.

TRENCH FEVER

BY

Sir ARTHUR HURST, D.M., F.R.C.P.

It is generally stated that trench fever appeared for the first time during the war of 1914-18 and that it then disappeared, never to be seen again. But there is good reason to believe that the disease had long been endemic in parts of Poland and that it has persisted there until the present day, although it was regarded as a form of malaria or influenza by the country doctors, who alone were familiar with it. References to a *febris quintana* appeared in the Russian literature a century ago, and the Moldavia fever described by Dehio as occurring during the Russo-Turkish War in 1877 was almost certainly trench fever. Franke stated that he was familiar with the disease at Lemberg, in Galicia, before the last war, but that it was thought to be a form of influenza. The first German reference to trench fever was made by His in February, 1916; he described it as *febris wolhynica*, having observed it among German soldiers in the Volhynia province of Poland, just to the north of Moldavia and Galicia. The short form was subsequently known in Germany as "gaiter fever" and the long form as "five-day fever," corresponding with the earlier *febris quintana* in Poland. Trench fever was probably conveyed by lice-infested German soldiers from the eastern to the western front early in 1915, quickly spreading to the British and French Armies in France and Flanders, where its specific nature was recognized by Graham, and subsequently by Hunt and Rankin and by McNee, Renshaw, and Brunt, a year earlier than the first observations recorded by the Germans and the French and two years earlier than those of the Italians.

The clean clothes provided for all soldiers admitted into British hospitals prevented the conveyance of the infection to their homes when they went on leave, so that it never reached the civilian population in England. After the armistice the small army still remaining on the Continent lived under such good hygienic conditions that lice infestation, and with it trench fever, quickly disappeared, and no further cases developed after the first few weeks of 1919. Since that time it has never reappeared in the British Army. The low incidence of lice infestation in the Army in France in 1939 and 1940 would have prevented its development even if the disease had become endemic there; but it died out after the last war as quickly in all parts of Western Europe as in the British Army. Since it had never occurred in England, the herding of lice-infested people in air-raid shelters did not result in the appearance of the disease, as it certainly would have done in epidemic form had it been endemic in this country. There is, however, some evidence to show that trench fever remained endemic in Poland, though it was still not recognized as a distinct infection. In 1922 the extracellular rickettsia, *R. quintana*, which is believed to be the causal organism, appeared among the stock of 350,000 lice maintained for experimental work on typhus fever in Weigl's Pathological Institute in Lemberg, where it caused an outbreak of fever among the 50 people employed as feeders for the lice. The infection was named Weigl's disease, but it was clinically indistinguishable from the short form of trench fever. A similar event occurred in the same Polish laboratory again in 1939 (Herzl). It seems likely that the laboratory stock of lice became contaminated by the blood of feeders who had contracted the infection in Lemberg, where Herzl during the second epidemic actually isolated the organism in two patients unconnected with the Institute who were thought to be suffering from influenza.

If Weigl's disease is actually trench fever and if it has really continued to be endemic in Poland in the period between the two wars, there can be little doubt that it must have reappeared in the lice-infested Polish, Russian, and German armies. An epidemic of typhus fever is said to be raging in the German Army in Poland, the Ukraine, and the Baltic States, particularly Lithuania. A German announcement in December, 1941, explained that typhus-bearing lice had become more numerous and dangerous since winter began because of the difficulty of keeping clean and because the thicker clothing then worn harboured more lice, and official Russian reports describe the almost universal lousiness of German prisoners. A newspaper published in Cracow has recently stated that all schools in Volhynia, where trench fever was first recognized among German soldiers in the last war, have been closed because of the danger of a typhus epidemic among the children. As trench fever, like typhus, is conveyed by a lice-borne rickettsia, it seems likely that a trench fever epidemic would appear simultaneously; but the comparatively trivial symptoms might well not be recognized as those of a distinct disease by medical officers working in hospitals crowded with men seriously wounded or suffering from typhus. As I have been unable to discover whether trench fever was recognized by the Russian Army doctors during the last war, although it is certain it must have been at least as common among Russian soldiers as among the soldiers of the other European armies, it is natural that nothing should be known here as to whether it has reappeared in epidemic form during the present war. The fact remains that it will be of the utmost importance to keep British soldiers free from lice infestation if at a later period they come into close contact with the Russian Army in the Caucasus or elsewhere, not only in order to prevent typhus but also to prevent the much less serious but none the less incapacitating trench fever.

Trench fever first appeared in the British Army in France in the early summer of 1915. Its incidence rapidly increased until it accounted for about 15% of admissions into the clearing stations for all forms of sickness. It was estimated that about 45,000 per million men were lost each year by evacuation to the base on account of trench fever, and that 90% of them were off duty for at least 3 months. It did not occur in Gallipoli, but was brought to Salonica in December, 1915, and to Mesopotamia in May, 1916, by divisions which had previously served in France.

Pathology

It was soon recognized that the infection of trench fever was lice-borne, and later investigations showed that it was caused by a rickettsia, *R. quintana*, which develops in the lumen of the louse's gut, in contrast with the rickettsia of typhus, *R. prowazeki*, which invades the epithelial cells of its wall. Rickettsia is a well-defined group of minute living organisms, the position of which in relation to bacteria and viruses is still uncertain. *R. quintana* multiplies in the louse's gut and is then excreted in the faeces. It is transmitted to man when an area of skin on which the infected lice have been crushed is scratched. The conditions of life in the trenches naturally resulted in its incidence being much higher there than at the base, but cases occurred among hospital orderlies and occasionally in areas some distance from the front line.

Symptoms

The incubation period is between 15 and 25 days. Trench fever generally begins suddenly without premonitory symptoms, but it is occasionally preceded by a feeling of malaise for a day or two. The earliest symptom is a severe headache, especially frontal and behind the eyes; this is rapidly followed by pain in the lower part of the back and, on the second or third day, in the legs. The onset is sometimes extremely abrupt: the patient suddenly feels giddy and his legs give way under him. He may be very short of breath. He has to fall out if marching, and often has great difficulty in returning to camp without assistance. Pain in the neck may occur; it is occasionally accompanied by stiffness and may be severe enough to suggest the presence of meningitis, which cannot be excluded without lumbar puncture. The patient generally shivers at the onset, but there is never a definite rigor. He is sometimes flushed and often sweats profusely. The bowels are regular or constipated, and there is no nasal or bronchial catarrh. The appetite is lost, the tongue is moist and often slightly furred, and occasionally mild pharyngitis is present. Herpes labialis sometimes occurs. There is usually no rash. The shins are always tender, even if the patient complains of no pain in the legs, but there is no muscular tenderness. The pressure of puttees may be enough to cause pain, and the patient often removes them in order to relieve his discomfort. In the first attack of pyrexia the spleen is sometimes palpable. Leucocytosis is often, but not always, present during each febrile period.

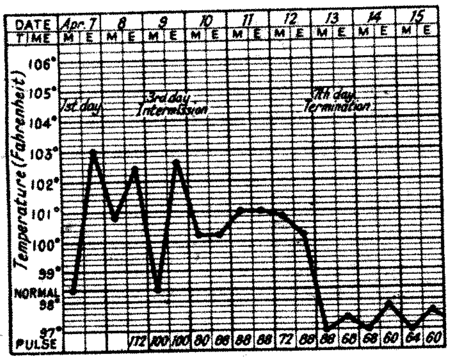

FIG. 1.—Temperature chart of the short form of trench fever.

In the short form of trench fever the temperature rises rapidly to between 102° and 104°, but the pulse rate is only slightly increased (Fig. 1). On the third or fourth day the temperature sudddenly falls, generally to normal or subnormal, but there is no corresponding improvement in the symptoms. After an interval of a few hours it rises again, and then after another 2 to 5 days it falls to normal. On this occasion there is immediate relief from all of the symptoms. Sometimes the remission on the third or fourth day does not occur, the temperature remaining raised for about a week. There is often a single relapse after an interval varying from a few hours to 10 days, but generally less than 4 days; the temperature rises to 100° or 101° for 24 to 48 hours, during which the symptoms return with diminished severity. The patient is usually fit for duty almost immediately after the temperature falls again.

In the long or periodic type of trench fever the temperature rises to between 101° and 104° on the first evening (Fig. 2). The initial attack is variable in duration: the temperature may be normal the first morning, high in the evening, normal the second morning, and rather less high the second evening than the first, after which it remains down. In other cases the first attack may last as long as 4 or 5 days, the temperature always being lower in the morning than the preceding and following evening, and reaching its maximum on the second or third day. With the fall in temperature at the end of the initial attack all the symptoms disappear. After being well for from 2 to 10 days the patient complains of a return of headache and pain in the legs which culminate at night; the temperature rises in the evening to a point that is generally a little lower than the highest temperature in the first attack. The temperature falls to normal or nearly normal the next morning, and either remains down or rises to a less extent the second evening, thereafter to remain normal. The general symptoms are much less severe than in the first attack, but the pain in the legs and the tenderness of the shins are usually greater, and they may not disappear completely in the interval between the second and third attacks, though the headache, which generally remains the most prominent symptom during the attack, is never present in the apyrexial periods. The pain in the legs is sometimes extreme and may prevent sleep. In other cases it is comparatively slight, and the patient looks and feels remarkably well considering that he has a temperature of 101° or more.

Recurrences follow periodically, the maximum temperature always being reached in the evening. The intervals between the attacks are fairly constant in each case, but vary in different cases between 4 and 8 days, 5 being the most common. As a rule each succeeding attack is milder than its predecessor and the temperature is rather lower, but in severe cases the patient feels weaker in the later intervals and the pain and tenderness of the legs are more persistent. The later attacks may be of such short duration that the rise in temperature is not recorded at all if it is taken only twice a day. On the afternoon and the evening of the day on which the attack is expected the temperature should therefore be taken every 2 hours, especially if there is any pain in the head or the legs, as in most instances the patient knows from his sensations that there is going to be a relapse even before the temperature rises. The temperature is sometimes raised for only 3 or 4 hours.

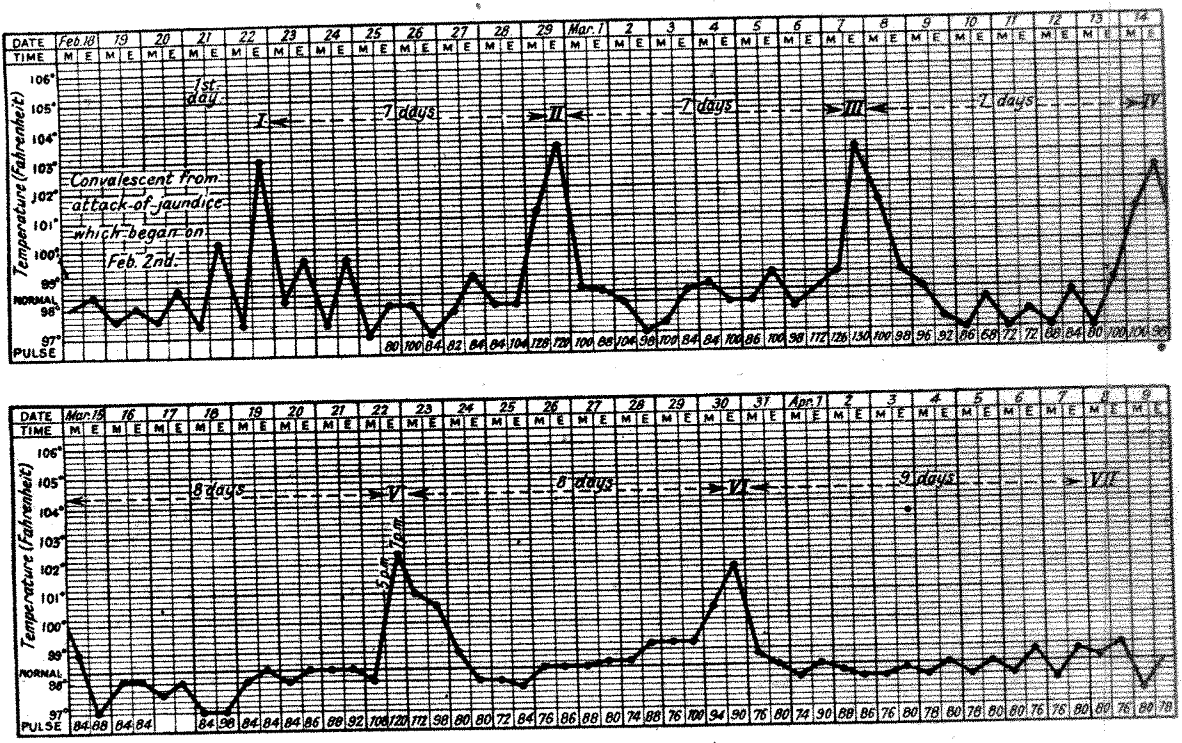

FIG. 2.—Temperature chart of the periodic form of trench fever.

Diagnosis

The diagnosis can be made with certainty from a study of the temperature chart, but the association of pyrexia with tender shins is already very suggestive of trench fever in the first attack. The majority of cases were at first diagnosed as influenza, though it was generally recognized that they were not identical with the familiar forms of that disease. Thus there was never any nasal or bronchial catarrh, the patient rarely appeared or felt seriously ill, except sometimes during the first two days of the first attack, and respiratory complications never occurred. The periodic return of pain and pyrexia, and the pain and tenderness of the shins, are quite characteristic and prevent confusion with influenza except at the onset.

The diagnosis from dengue fever may be very difficult, especially in tropical and subtropical coastal and inland river areas, where the vector of the latter—a mosquito, *Aëdes aegypti*—abounds. The onset of dengue is sudden; the temperature rises rapidly to 102° to 103°, dropping by crisis 3 or 4 days later, but often rising again for 2 or 3 days after a short interval. Severe backache and joint pains occur, and a rash, described as half-way between that of measles and scarlet fever, develops during the second pyrexial period.

The possibility of malaria must always be considered, and in cases of doubt a blood film should be examined for the malarial parasite before making a definite diagnosis, especially if the patient has previously had malaria and in countries where it is prevalent. The longer intervals between the attacks, their invariable occurrence in the evening instead of at various times of the day, the absence of true rigors, and the failure of quinine to modify the course of the illness are distinguishing features of trench fever.

A few cases of true spirochaetal relapsing fever occurred in British troops in Gallipoli, Egypt, and Salonica. The initial pyrexial period was usually longer than in trench fever, varying between 5 and 7 days, and the maximum temperature was often over 104°. In most cases only a single relapse, lasting between 3 and 5 days, occurred after an interval of from 8 to 10 days. Headache was severe, and pain was present in the muscles and the joints of the legs, but not especially in the shins. Slight jaundice, slight enlargement of the liver, and albuminuria were often present. The spirochaete was found without difficulty in the blood during the pyrexial stage.

Prognosis

There were no fatal cases of trench fever, and the patient never appeared seriously ill, except occasionally for a very short time in the first pyrexial period. The total duration of the periodic type from the onset to the end of the last attack was generally between 4 and 6 weeks; but some cases appeared to abort, and in a few others attacks recurred for several months, the patient remaining quite well in the intervals. In most cases the patient rapidly recovered his strength after an attack, and was usually fit for duty after the second period of pyrexia, though he might have to rest for a few hours when the later attacks occurred.

Patients with trench fever who were kept in base hospitals too long, especially if they were transferred to hospitals in England, showed a great tendency to become chronic invalids, and large numbers were eventually discharged from the Army as cases of "neurasthenia" and "D.A.H." The former complained chiefly of exhaustion, irritability, headache, and pains in the legs and back, the latter of breathlessness on exertion, palpitation, precordial pain, giddiness, and fainting. I am convinced that the neurasthenia and D.A.H. were only to a minor degree a direct result of the toxaemia of trench fever and were mainly functional and preventable conditions. They developed most frequently in hospitals where over-conscientious medical officers were too much impressed with what they took to be a slight enlargement of the heart or an apical systolic murmur, and where an over-sympathetic nursing staff in English V.A.D. hospitals was too much impressed with complaints of fatigue and general unfitness. There was a remarkable difference in different hospitals in both France and England in the average stay of patients with trench fever coming from the same units, and my impression was that a long stay in hospital was the cause and not the result of a case becoming chronic. I do not think that there was ever any justification for invaliding a man from the Service for trench fever, and no cases need be allowed to develop either neurasthenia or effort syndrome.

Prophylaxis

As trench fever is conveyed by lice, which become infected by biting a patient during an attack, it should be possible to prevent the disease by keeping troops free from infestation. All cases should either be sent to hospital or be isolated, and the patient's clothes and bedding should be specially disinfected as well as that of all men who have recently slept near him. After the initial or the second attack a man is often able to return to duty. It is very important that he should be kept under observation, and if he again becomes lice-infested his clothes and bedding should again be disinfected.

A determined attempt to prevent the reappearance of trench fever in the present war is being made by the provision of sufficient baths, laundries, and vermin destroyers, and this has so far proved completely successful (August, 1942). Between 1914 and 1918 men were often crowded in dug-outs and cellars and could change their clothes or bathe only at rare intervals, with the result that lice-borne trench fever spread. Although measures to exterminate lice were energetically pursued from an early stage of the last war, it was not until the middle of 1917 that equipment and facilities were sufficient to have any obvious effect in reducing the incidence of trench fever.

Treatment

No treatment was found which prevented the periodic return of attacks. Aspirin was the most effective drug for the pains. It is of great importance not to keep the patient in hospital longer than is absolutely necessary. He should be sent as soon as possible to a convalescent depot, where fresh air, good food, and progressive exercise quickly restore him to full capacity, so that he is able to return to duty. If possible he should not be sent to hospital in England, as the longer he is in hospital the less likely is he to recover rapidly and completely.

The accompanying charts are reproduced from Sir Arthur Hurst's *Medical Diseases of War*, 2nd edition (Edward Arnold and Co.).

MEDICAL RESEARCH COUNCIL OF IRELAND

It is complained in the annual report of the Medical Research Council of Ireland that the income placed at the disposal of the Council—namely, £5,000 from the Hospitals Trust Board, guaranteed by the Minister of Local Government and Public Health of Eire—is not adequate for the efficient discharge of its functions. The absence of any assurance that the endowment will be continued for a long period makes it impossible to plan for more than a year in advance or to invite at frequent intervals the services of new workers. It is hoped that when it approaches the Minister for renewed support he will find himself justified in making arrangements of a more liberal and stable character. Among the investigations carried out during the year by means of grants from the Council was a survey of the distribution of vitamin C in the Irish natural food products and emergency sources, together with a study of vitamin supplies and requirements under present conditions. This is being done in the Department of Biochemistry, Trinity College, Dublin. In the School of Pathology at Trinity, grant-holders of the Council have shown that the addition of talc or any one of some twenty insoluble inorganic substances renders distilled water capable of supporting the growth of coliform and similar bacteria. These substances also render tap water growth-supporting. It is suggested that talc makes available for the growth of these organisms carbon dioxide and ammonia derived from the atmosphere, and work is being continued to investigate this theory. In the Department of Chemistry, University College, Cork, an investigation is proceeding into the prevalence of goitre in Tipperary, especially the distribution of goitre among school-children and the influence of iodine treatment upon the prevalence of the condition. Balance experiments have been undertaken to ascertain the influence of certain foods on the excretion of iodine, and suitable methods for the estimation of calcium and phosphorus excretion, with a particular study of their possible relation in goitrous conditions, have been worked out.

SURVEY OF SCOTTISH HOSPITALS

Hospitals in the West of Scotland are to be surveyed as a first step to what may become an all-Scottish hospital census that will provide a background of collated information for any projected scheme of reorganization after the war. The surveyors, appointed by the Secretary of State for Scotland, are two Glasgow University professors—Prof. J. M. Mackintosh (Chair of Public Health) and Prof. C. F. W. Illingworth (Chair of Surgery)—together with the Senior Deputy Medical Officer of Health for Glasgow (Dr. R. J. Peters). Their task, which is expected to last six months, will be to investigate the accommodation, organization, equipment, staffing, and the number and origin of patients treated in the general and special departments of West of Scotland hospitals. The survey will be complementary to the work of the Sir Hector Hetherington Committee now inquiring into and reviewing questions of principle likely to be involved in a large-scale hospital reorganization. When complete the survey will show the facilities each hospital possesses and the part it will be capable of playing in an integrated hospital service. A start has been made in the West of Scotland because it is the most populous area and contains a large number of hospitals of all kinds, the co-ordination of which into a regional service will present greater difficulties than will arise in other areas of Scotland. Prof. Mackintosh before taking up his university appointment was Chief Medical Officer of the Department of Health for Scotland; Prof. Illingworth is honorary surgical director in the West of Scotland of the Emergency Medical Service.

Correspondence

Medical Planning: the Main Issue

Sir,—One sentence in para. 24 of the report of the Medical Planning Commission summarizes the main issue with which the profession is faced. It runs as follows: "This involves the integration of the preventive and personal health services." If this principle is accepted as the basis of the medical service of the future, it is useless to put forward schemes which make no effective provision for such integration. The establishment of health centres as envisaged in para. 69 would effect co-ordination of services but would introduce a State service in a modified form, with the reduction of free choice of doctor and competitive practice to a minimum.

Those members of the profession who are opposed to any form of State control have two alternatives. They must either produce a scheme for the integration of preventive and personal services which will be free from control by statutory health authorities, or they must persuade the nation that "free choice," "competitive practice," and "freedom from bureaucratic control" are of more value to the medical service of the future than the integration of the preventive and personal factors of which such a service is composed.

It is to be hoped that the A.R.M. and the Panel Conference will meet the problem in a spirit of realism, bearing in mind para. 69 of the report, in which a definite choice is made in favour of health centres provided by statutory health authorities. Nothing will be accomplished by handing the baby back to the commission with a blessing on voluntary "group practice" but with no precise indication as to how this will achieve the objective which is so admirably summarized in para. 24.—I am, etc.,

Bury St. Edmunds **Bernard E. A. Batt.**

Planning, Research, and Autonomy

Sir,—In giving general support to the recommendations of Dr. Milligan and Dr. Simpson (Aug. 22, p. 227), I suggest that the "active intelligence service" of the former is necessarily related to "the research army working in the field" of the latter. An "intelligence service" operating in local or regional areas should perform functions similar to those discharged for the country as a whole by the M.R.C. It should also perform functions that are not performed at present by any body. There is room for a considerable degree of local autonomy in clinical and experimental research and for a still larger measure of local freedom in conducting "medical inquiries," which should precede "research." But this local freedom should be subject to advisory and financial control from the centre—that is to say, from a central medical inquiry and research council.

The functions of a regional council or unit would be: (1) inquiry into the facts concerning illness and disability in the area; (2) inquiry into the facts concerning local health conditions, etc.; (3) inquiry concerning the diagnosis, prognosis, and therapy of illness, etc., within the local area; (4) to maintain liaison between the regional and central councils; (5) to co-operate, on request, in carrying out inquiries or research initiated and conducted by the central council. The personnel of the regional or local councils should be drawn from all sections of the medical services, and contact should be established with a number of non-medical organizations concerned with health (industry, labour, and benefit and insurance societies, etc.).

I hold it to be as essential to preserve a real measure of freedom in the local bodies as it undoubtedly is to co-ordinate their work. It is still more important to set up a centre to which local practitioners can refer their problems, discuss tentative hypotheses, and be encouraged and guided in the search for fuller knowledge. These regional or local councils or centres will have to be established on a voluntary basis in the first instance.—I am, etc.,

Worcester **Howard E. Collier, M.D.**

Epidemic Problems in Wartime

Sir,—Your leader on post-war epidemic problems (Aug. 8, p. 161) rightly stresses the necessity for setting up co-ordinating machinery before the war ends so that no time may be lost in dealing with the most urgent problems of epidemics. In the midst of post-war Utopias which are conjured up around us it is good to hear sound advice on the need for laying foundations for post-war reconstruction of all kinds before the war ends. This is especially true of epidemics.

We should never forget the lessons of the last war. Then, nothing was done to establish co-ordinating machinery before the Armistice or even before peace was signed. In Eastern Europe I took some part in initiating measures and can therefore testify to the difficulties which threatened to swamp us because such measures were taken too late. There was almost total lack of co-ordination, and the fight against epidemics was taken up by various independent bodies such as the Rockefeller Foundation, the Society of Friends, the League of Red Cross Societies, the International Health Board, and, much later, the Council of Hygiene of the League of Nations. The result of such lack of cohesion was a devastating spread of epidemics which killed five times as many souls as had fallen victim to bloodshed during the war itself.

Such a calamity must be avoided to-day, especially as, according to all forecasts, epidemics threaten to be even more extensive than after the last war, because they will fall on populations that have reached their last stand of resistance. I believe that even England will not be immune. The need for establishing immediately the appropriate machinery for fighting all foci in the various countries of Europe has been considered, at my suggestion, by the Inter-Allied Red Cross Conference. As the Red Cross societies, thanks to the centralizing work of the International Red Cross, are the only bodies that can set up without delay an international machinery to combat European epidemics, a subcommittee has been instituted by the Inter-Allied Red Cross Conference to deal with these matters. Medical men all over the world should give their support and help, and it is to be hoped that the Red Cross societies will be able to carry out their great humanitarian task, and, by taking measures against the foci of epidemics occurring now, will prevent their post-war spread and thus the destruction of Europe.—I am, etc.,

A. P. Cawadias, M.D., F.R.C.P.

London, W.1 President, Greek Red Cross.

Serodiagnosis of Syphilis

Sir,—Several letters have appeared in the *Journal* dealing with the question of serological tests for syphilis following your annotation (March 14, p. 364). We have thought that an interchange of information on the subject might help workers in this particular field. We heartily agree with the author of the editorial article that: "The diagnosis, tests of cure, and exclusion of syphilis are of such importance both to the State and to the individual that none but the highest standards should be acceptable and every laboratory performing serum tests for syphilis should make it a point of honour to maintain these standards."

It stands to reason that much depends upon the way in which a test is carried out, and, as several of your correspondents have emphasized, the matter of serological tests for syphilis should not be in the hands of a technician alone. Moreover, it is much better to concentrate work of this kind in one large centre than have it scattered through small hospitals where there is inadequate supervision. It is, further, advisable that standard reagents should be supplied to approved laboratories, and that technicians should be trained in central serological institutions before undertaking this type of work.

The Department of Health of the Province of Ontario under Dr. A. L. MacNabb has elaborated a combination of methods as follows: The sera are subjected first to a screening (sifting) test which will eliminate all negatives and separate the positives and possibly some false positives. The method employed is the "presumptive Kahn procedure," using an antigen with its sensitivity adjusted so as to pick out the minimum quantities of "syphilitic reagin." If the result of this test is negative, the specimen is reported immediately as negative. If, on the other hand, any reaction at all occurs, no report is issued until a standard Kahn and a Kolmer-Wassermann test have been performed. If these two additional tests are both positive a quantitative Kahn test is performed and a positive report in terms of Kahn units is issued. Thus presumptive positives are submitted to three additional serological tests before a positive report is sent out. If there is any discrepancy between the Kolmer-Wassermann and the standard Kahn, or if the results of the two tests are doubtful—e.g., one plus—the specimen is reported as doubtful and a further sample of blood from the patient is requested. If the two additional tests are both negative, a negative report is issued and a further specimen is requested from the patient.

It might be considered that this routine is an unnecessary elaboration and possibly a waste of time, but too much trouble cannot be taken to eliminate the false positives, and the amount of work and the apparatus used are definitely less than would be required if two standard methods were routinely employed on every specimen of serum submitted. The vast majority of sera are negative and are ruled out by the highly sensitive screen test necessitating only one tube. Time is concentrated on the examination of the relatively few positives or possible positives.

Using the above technique a staff of four technicians and one pathologist can easily put through 500 sera a day. The major part of the time expended is connected with entering the speciments and typing the reports, not with the actual serological tests.—We are, etc.,

Hereditary Factor in Cardiovascular Disease

SIR,—Referring to the annotation under this heading (Aug. 1, p. 135), the pathology of inheritance is dealt with by Freiherr von Verschuer, at the time (1934) head of the department for anthropology, human inheritance, and eugenics at the Kaiser-Wilhelm-Institut, Berlin-Dahlem, in his work *Erbpathologie*. There may be a later edition. He deals with a very large number of diseases, defects, or abnormalities in a chapter on special pathological inheritance, pride of place being given, as might be expected, to nervous and mental disorders. Interesting and instructive, the need for much more work is, however, apparent.

As regards cardiovascular disease, while pointing out that in heart disease environmental conditions are operative in the majority of cases, authorities are quoted for the statement that there are families in which inflammation of the cardiac valves is very frequent; a hereditary basis, it is stated, plays an undoubtedly important role in these. Heart form and heart function are claimed as having such a basis, on the ground of work cited, which included observations on identical- and non-identical twins.

As regards arteriosclerosis and hypertension, I should expect inquiry among experienced family doctors to elicit that there is a family frequency in these conditions, associated with cardiac and renal disease, and tendency to early apoplexy—a hereditary element. If so, it would but emphasize the need for replacing impressions by reliable family histories on a uniform basis, to procure which a formidable amount of post-war planning will be necessary; to shirk this task would mean faint-heartedness and lack of vision. As to arteriosclerosis, von Verschuer confirms that in many families it occurs with frequency. In such it may be of a general kind or show preference for definite vascular areas, so that in some families cerebral vessels are affected: others show angina pectoris, or the renal vessels may be the seat of election. Authority is cited for these statements.

I quote from your annotation concerning cardiovascular disease: "When both parents died from other causes the percentage of policy holders dead from cardiovascular disease was 51; when the father died from cardiovascular disease, 57; when it was the mother, 56; and when both parents died from cardiovascular disease, 65. And from Weitz (quoted by von Verchuer) concerning hypertension:

One or Both Parents Died of Stroke or Heart Disease at Age	Of 82 Hypertonics	Of 267 Controls
To 50 years	11.0%	2.6%
From 51–60 years . ..	15.9%	5.6%
„ 61–70 „	36.6%	12.7%
Over 70 years	9.8%	9.4%

Further, after age 55 about half the brothers and sisters of the hypertonics suffered from or died of hypertonia. The condition could often be followed in direct succession through several generations (dominant inheritance). Inquiries in the case of twins, by authors quoted, show that in the matter of blood pressure the similarity between identical is clearly greater than between non-identical. Similarity is greater with increasing age in identical twins; dissimilarity in non-identical.

Such studies are required in increasing measure to enable us to estimate the degree of importance of the basic factor of heredity in disease. In the particular case of hypertony they serve to explain those instances in which the state appears early in life—with resulting injury to heart, blood vessels, kidneys—without the operation of such external influences as syphilis, alcohol, gout, psychical disturbances, overstrain, nicotine, etc.—I am, etc.,

Hove.

EDWIN GOODALL.

Special Clinics for Diabetics

SIR,—I am glad to see that Prof. L. J. Witts (Aug. 22, p. 226) stresses the necessity for special clinics for anaemia and diabetes and for their consideration in medical planning. As regards diabetes, he will be glad to hear that the Diabetic Association, essentially a body of lay diabetics, has already asked the Planning Commission to take steps to establish clinics on a regional basis throughout the country, as it considers this essential for the welfare of its members and diabetics in general. It is probably a novel situation for a body of sufferers themselves to ask our profession to make special arrangements for treatment, but it shows how the wind blows. They know that their health and working efficiency depend on advice based on laboratory tests and special experience outside the scope of most doctors and obtainable only at special centres.

We should not wait for post-war planning as the need is urgent now. Such clinics are simple and inexpensive to start, the laboratory requirements not elaborate, and I am glad to say that, although still quite inadequate in number and in geographical distribution, they are opening up all over the country through the efforts of interested doctors.—I am, etc.,

Diabetic Clinic,
King's College Hospital.

R. D. LAWRENCE.

Urethral Instrumentation

SIR,—Mr. Gordon Bohn (Aug. 29, p. 259) raises important points and asks for other opinions. In my experience, with a benign enlargement of the prostate a first attack of acute retention rarely results in permanent retention; with a malignant prostate, however, the history is one of increasing difficulty in micturition, and when retention supervenes it is more commonly permanent. In the former case, after a varying interval, micturition is re-established but the patient does not empty his bladder; in many cases the bladder is infected, and this in spite of the most scrupulous asepsis. Once retention has occurred the patient is on the downward path, and should he live long enough operation will become a matter of necessity. Operation being inevitable sooner or later, it is best done early while the going is good. It is impossible to generalize; each case must be decided on its own merits, the age of the patient and his "prospect of life," his renal and cardiac condition, the amount of residual urine, and whether it is infected or not, all being carefully weighed. Early operation gives better results and a lower mortality. Chronic retention resulting in overflow incontinence is in a different category, and after slow decompression operation is not a matter of expediency but one of necessity. Chronic retention is a much more serious condition than acute retention because the kidneys have been subjected to a long, slow, increasing back-pressure. Mr. Bohn's views will surely be endorsed by all urologists, and it should be an axiom that with bad vessels, a high blood pressure, or low-specific-gravity urine, slow decompression is vital, and catheterization should be considered a serious operation.—I am, etc.,

London, W 1. SYDNEY G. MACDONALD.

Sphincter Mechanism of the Bile-duct

SIR,—In the early part of your leading article (Aug. 8, p. 161) on the Hunterian Lecture given by Rear-Admiral Gordon-Taylor, you refer to the duodenal villous processes, but I take it that "duodenal" has here no special significance, and that you really have in mind the villous processes situated within the terminal portion of the common bile-duct. To these processes, with their core of muscle, Gordon-Taylor assigned the dual function of helping to control the exit of bile from the duct and preventing regurgitation from the duodenum. He emphasized the fact that an ampulla—the ampulla of Vater—is rarely present in man. *X*-ray examination with an opaque fluid passed into the common duct through a T-tube (cholangiography) confirms his opinion, for one rarely sees any distension of the terminal part of the duct. Gordon-Taylor and Prof. Kirk have kept the description of the sphincter within reasonable limits, but in the hands of others it becomes a thing of varying complexity in which at times three separate sphincters may be distinguished—i.e., a sphincter for the bile-duct itself, a sphincter for the pancreatic duct, and a sphincter for the so-called ampulla. The opinion expressed in your article that the flow of bile into the duodenum is irrespective of the duodenal movements would also seem to be supported by cholangiography. Some *x*-ray pictures taken for me show the opaque medium passing from the duct into the duodenum while the latter in strong contraction is forcing the dye not only downwards into the intestine but upwards into the stomach.

Much of the evidence against the sphincter has been obtained from experimental research in animals, but animals vary greatly in their biliary apparatus, some having gall-bladders with a good sphincter, while others have no gall-bladders and a sphincter which is negligible. It is much more to the point to study the evidence in man himself. I believe that much of the trouble for which the sphincter is blamed is really due to stones, or some condition such as biliary mud or grit. If the trouble is removed and the duct drained so that it and the liver may have a chance to recover, then I am sure much less will be heard of the failures of operation and less of the spasms of the sphincter.

For some years past I have made a practice of carrying out wherever possible cholangiographic investigations after exploration of the common bile-duct, and where stones have been removed and the bile-duct drained I have yet to see a case in which spasm of the sphincter has persisted after operation; the opaque medium can be seen to flow into the duodenum readily. To visualize spasm in such cases it is necessary to inject morphine, when the opaque medium can be seen to be held up abruptly at the termination of the duct. You quote Mirrizzi as saying that the ducts are dilated in these cases. Invariably they are, but to my mind this is due to back pressure caused by stones, and not to spasm of the duct. This is very clear in one of my cases where I had missed a stone in the duct; cholangiography showed a dilated duct with a stone obstructing its lower end, yet a thin stream of the opaque medium could be seen to flow past it and through the sphincter into the duodenum. In some cases where stones have been present in the gall-bladder but none found in the common bile-duct, cholangiography showed no increase of tone of the sphincter and no dilatation of the ducts. Puestow, from investigation of his cases which had undergone cholecystectomy and drainage of the common duct, found that not only was there absence of spasm of the sphincter but that there was strong evidence of decreased tone of the muscle.

If, as some assert, spasm of the sphincter is so pronounced in cases of stone of the common bile-duct, why is it that jaundice is absent in not less than 35 to 40% of cases (Lahey); and why is it that biliary colic and pain is absent in still greater proportion—according to Macdonald 56% of cases? Why also, it might be asked, is it that when drainage of the common bile-duct has been established for some time after removal of stones the drainage tube can be clamped without discomfort and bile flows readily into the duodenum? Finally, why is it that when the drainage tube is withdrawn a fistula does not persist and external drainage of bile ceases within 24 to 48 hours?

In any of the cholangiograms taken for me I have never seen evidence of a sphincter of the hepatic duct. On occasions the opaque medium has lagged behind in the hepatic duct and sometimes in the common duct, but closer inspection has shown the faint outline of the duct below with no evidence of muscular contraction. This bears out Gordon-Taylor's opinion that there is no sphincter of the hepatic duct, and is as one would expect, for, apart from the sphincter at the lower end of the common duct, histologists have found only occasional fibres of muscle irregularly scattered elsewhere in the bile-ducts.

I must confess that I have not been able to secure a picture of the duct of Wirsung in any of my cases. According to Mirrizzi this is a constant finding in cases of stone of the common bile-duct. Some of our cases have been misleading, and what was at first thought to be a shadow in the duct of Wirsung eventually proved on further *x*-ray examination to be dye which had passed into the stomach. I am rather inclined to think, however, that filling of the duct of Wirsung depends less on the presence of stone than on the anatomical arrangement of the sphincter, which on contraction in a small percentage of cases will put the opening of the common bile-duct and the duct of Wirsung into free communication. Otherwise one would expect acute pancreatitis to be a much more common disease.—I am, etc.,

London, W.1. MICHAEL J. SMYTH.

Atypical Asphyxial Deaths

SIR,—Dr. Norman Patterson's article (Aug. 15, p. 188) came most opportunely to confirm the findings of a similar case of sudden death which occurred in this mental hospital on Aug. 8. This would indicate that these accidents are not so very rare. As this case is of interest because there were three other possible causes of sudden death to be considered—epilepsy, valvular disease of the heart, and phthisis—the case history is given below.

A male patient was admitted in 1925, at the age of 25, suffering from primary dementia, and tricuspid incompetence of indefinite duration was then noted. He demented slowly and recently he could only sit about the ward. On several occasions he was put to bed as a result of cardiac decompensation. In 1939 phthisis was suspected but not confirmed. In May, 1941, he had two severe major epileptic fits during which he nearly died because of his poor cardiac condition; there were no fits before or after these two.

During his evening meal on Aug. 8 he was seen to topple forwards over the table, with no cry, twitching, convulsion, or struggle of any kind. He was unconscious when reached. I saw him within 5 minutes when he was still unconscious, with face blue and slightly congested, and respiration almost stopped at a rate of not more than 5 per minute. The pulse was regular and was of moderate force and volume. His mouth was crammed with soft unmasticated food, which was removed so far as possible with a spoon handle. Artificial respiration was then begun, but after two respiratory excursions the chest became rigid and no air could be made to enter or leave the lungs. The pulse thereafter deteriorated rapidly and stopped within a few minutes, death occurring within 10 minutes of the original collapse. The absence of any tonic or clonic contractions excluded epilepsy, and the regular moderate pulse ruled out a sudden cardiac failure.

A post-mortem examination was performed 20 hours after death. There was no external patchy lividity to indicate asphyxia. The nose was packed tightly with soft unmasticated food, a piece formed a ball-valve over the entrance to the larynx, and more filled the larynx, the bronchi, and larger bronchial passages. The lungs were normal and showed no signs of active or healed tuberculosis. The stomach contained one pint of food from the midday meal, and the presence of whole potatoes indicated the patient's feeding habits; no soft food from the evening meal could be distinguished. The heart showed tricuspid incompetence, an enlarged right auricle and ventricle with hypertrophied and fibrosed myocardium, but there was nothing to show that compensation was not adequate at the time of death. The left side was normal in appearance. The brain and other organs were normal.

Apart from the regular moderate pulse persisting for 5 minutes after the initial collapse, these post-mortem findings and the clinical history would conform to the theory that these sudden deaths are due, not to ordinary asphyxia, but to syncope following shock from the presence of inhaled food in the respiratory passages.—I am, etc.,

JOHN HARKNESS,
Pathologist and Medical Officer.

Royal Asylum, Montrose.

Rehabilitation

SIR,—Mr. H. Morriston Davies has surely done well in calling attention to what he describes as the tragic consequences of the attitude of the Ministry of Health in connexion with rehabilitation centres as expressed by Sir Robert Stanton Woods in the statement by him which Mr. Morriston Davies quotes. If Sir Robert's statement truly represents the policy of the Ministry on this important question, one cannot help wondering if such policy is based on inadequate or wrong advice. The future of physical medicine lies undoubtedly in institutional treatment centres, because it is impossible without such institutions to cater for the numbers of injured members of the Services and war workers who are to-day left for unduly long periods in a state of complete or partial inefficiency owing to the lack of adequate facilities for the requisite treatment.

The initial cost of rehabilitation centres is usually put forward as the main block to progress in this direction, but, in actual fact, I firmly believe, in spite of the cost, the formation of such centres would constitute a sound economic procedure. The immense saving of money which would normally accrue from being able to return an injured man to his work at the earliest possible moment would be considerable. In addition, the opportunity for adequate treatment for restoration of function as soon as possible would materially lessen the likelihood of a worker's acquiring a permanent disability, as all too frequently happens, and an industrial man-power loss and much of the expenditure required to compensate him would be saved.

If Sir Robert's statement that "after the war it is almost certain that such institutions will be found necessary" is also the view of the Ministry, one can only have a feeling of despair at the opportunities that will be missed while the war lasts. If it be a fact, which surely few will dispute, that it is the inherent right of all sailors, soldiers, and airmen, war workers and members of the public injured by enemy action, to have opportunities accorded to them for treatment by the most modern methods, this attitude of waiting till after the war would seem to be quite indefensible.

Mr. Morriston Davies's letter raises another point regarding the meaning of the word "rehabilitation." It would appear that the public, and in particular certain members of Parliament and of the medical profession, are under the impression that rehabilitation is a newly discovered *method* of treatment for injury and disease, which it certainly is not. Rehabilitation means, when used in a medical sense, "restoration to a previous condition," and is therefore essentially an "end result" brought about by treatment by medical, surgical, or physical-medicine procedures. Such procedures are the agencies leading to a "state of rehabilitation." The use of the word "rehabilitation" in the sense of a *method* of treatment is confusing and will give a wrong impression to the uninitiated; and if in the future, as many of us hope and believe, rehabilitation centres or industrial clinics are established in many industrial parts of the country, it would be a pity if the public are misled into believing that such centres are places where a new method of treatment only is practised instead of a centre for rehabilitation of patients by all or any of the most modern methods of treatment.—I am, etc.,

MORTON SMART.

London, W.1.

SIR,—One sympathizes with Mr. Morriston Davies's concern over the facilities provided for "rehabilitation" under the Ministry of Health Emergency Hospital Scheme, a concern which has obviously arisen as a result of my own inadequate description of this provision in your issue of July 25. It was, however, made clear in that, necessarily short, summary that *very extensive* facilities for this exist at E.M.S. hospitals. After prolonged consideration the Rehabilitation Committee of the Emergency Medical Service decided against the establishment, during the war, of separate "centres" whose sole function would consist in the post-hospital treatment of civilians, a decision with which I am in agreement. Such centres would of necessity be, in many cases, residential.

In E.M.S. hospitals, Service and civilian sick and casualties begin rehabilitation in bed and as early as is safe and advisable, and progress through graduated stages until their discharge from hospital. Service patients continue their post-hospital rehabilitation in residential centres; in the case of civilians, patients attend from their own homes at the very numerous hospitals and clinics which have been either established anew or selected on account of their already existing facilities.

I feel sure that, on reperusal of a necessarily condensed description, Mr. Morriston Davies will realize that the sentences quoted in his letter confused two items of entirely personal advocacy—namely, the establishment *after the war* of residential centres for the rehabilitation of civilians, and some remedy for the present scarcity of medical men and women with experience of this work.—I am, etc.,

ROBERT STANTON WOODS.

Self-medication and the Chemist's Shop

SIR,—Dr. Loewenthal has made some excellent suggestions for curbing that most undesirable practice—"counter-prescribing" in chemists' shops. In the past the vested interests in the patent medicine industry have proved themselves immensely strong, but if the medical profession were sufficiently insistent now, legislation might be introduced with success. The opportunity is unique, when improvement in the health of the nation is of first importance in the prosecution of the war. Must we wait for a professor of social medicine to tell us what we know already, that "counter-prescribing" is responsible for a great deal of chronic illness and many deaths? Only a week ago I watched the sale of patent medicines at a street market in a large Midland town. A special line at 3s. 6d. a bottle was for St. Vitus's dance, and a cure was guaranteed in 3 weeks.—I am, etc.,

F. L. KING LEWIS.

SIR,—Dr. E. L. Loewenthal has written a most important and necessary letter. I venture to differ from him only on minor points and in that I would go further. First, the points of difference: "Big business" (I am in no way financially interested in it) has given a phenomenal impetus to pharmacological research, and, in my view, has secured its truly remarkable results not only by the expenditure of capital but by putting behind its research men the peculiar acumen and enterprise which are characteristic of business. I have experienced this both outside medicine and as an industrial medical officer, and I would like to see it encouraged rather than repressed, but with these safeguards. First, any discovery should be rigidly protected so that the firm concerned reaps a reasonable reward and so retains its incentive; secondly, all formulae and methods would have to be honestly and completely revealed under heavy penalty; thirdly, rigid accuracy and truthfulness in all brochures, circulars, descriptions, advertisements, etc., to doctors and chemists would be obligatory under crushing penalty; and, lastly, as Dr. Loewenthal insists, sale to the public except on prescription would be prohibited. My second difference is on a financial matter. Most people, as I know well, simply cannot afford to pay the doctor and the chemists as well. Any reform must take account of this, for, from the point of view of the most important person of all, the patient, it is the very crux of the whole matter.

There is, however, a more ugly side to this scandal, and that is the fact that so many of us simply neither prescribe nor dispense at all. We simply "dope out" stock mixtures, and, for myself, I would in case of illness as soon lay out a half-dozen patent preparations, select one of them by cutting a pack of cards, and take my chance on the one which turned up as swallow some of the "mist. this" and "mist. that" which are foisted upon the people who chance the doctor instead of the chemist. Hard words, perhaps, and not very temperately put, but when I was doing research in collateral subjects soon after qualifying I kept my hand in at medicine by doing a series of one-week "locums." I did many in various parts of the country, and the recollection of some of those dispensaries and methods is still with me these 17 years after. Slackness and cost, and scamped and hurried teaching are at the bottom of the reaction against drugs which is fashionable just now. Surely materia medica, pharmacology, and therapeutics are in importance not behind anything else we ought to be made to remember? I am convinced that if all of us had to keep our knowledge of these vital subjects fresh and up to date the "stocks" would all but disappear. It is certain that the manufacturer and the wholesaler would cease to vend them as soon as we stopped buying and/or "prescribing" them. Is it any wonder that many chemists do not regard their advice as being materially more dangerous than that of some of the doctors whose "prescriptions" they dispense? Our own ineptitude at the time of the introduction of the N.H.I. Acts is as much to blame as anything else, for we allowed the panel doctor to become a sweated worker with inevitable results to most of us. We tacitly admitted that medical attention was such a casual and unimportant thing that a man could dispose of a patient in five minutes or less. I do not digress, for this is an intrinsic part of the problem.—I am, etc.,

Sheffield ANDREW KEFALAS.

Emergency Blood Transfusion Scheme

SIR,—The standardization of the apparatus for blood transfusion is altogether desirable and is not the least among the benefits arising from the organization of the Emergency Blood Transfusion Scheme of the Ministry of Health described by Dr. L. W. Proger (Aug. 29, p. 252). It has one by no means insurmountable disadvantage. A large number of hospitals are in the habit of obtaining their supplies of saline solutions for intravenous infusion in the standard pint bottle with spring cap used by many firms of manufacturing chemists for this purpose; others use these bottles for the preparation of their own solutions. Certain hospitals before the development of the Emergency Blood Transfusion Scheme also used these bottles for purposes of blood transfusion. Under these circumstances, the same delivery apparatus could be used for the infusion either of saline solutions or of blood, or, if desired, as is not infrequently the case, of either alternately. Owing to the great difference between the size of the mouths of the Emergency Blood Transfusion Scheme bottle and the standard saline bottle this is no longer possible.

There are many occasions in both civil and military practice on which infusion of a saline solution rather than of blood or plasma is required, or on which it may be desired to alternate the two. Would it be reasonable to suggest that, having provided both blood and plasma in standard bottles, the Emergency Blood Transfusion Scheme should further make available saline solutions in the same bottles?—I am, etc.,

Wolverhampton. S. C. DYKE.

Food, Farmers, and Health

SIR,—A patient who ran away from a mental hospital sent for me, of course to complain: "The treatment is abominable, or, rather, there is no treatment—except a black draught once a week. But for that I should never be moved at all: I go a whole week without; and can you wonder? We get some sort of meat and a great pile of potato and always rice pudding; never any second vegetable except—twice a week—a sad, sodden spoonful of cabbage. I feel awful. I used to get salad before I went there, salad twice a day, and I felt fine." That was the effect of his words. Next day I saw a consumptive man on leave from a tuberculosis colony—"A lovely spot," I remarked. "Ye-es," he said, "it would be all right if they'd give us some vegetables. We never get any"—this of an old estate in the depth of a farming country. "When I used to get lettuce and dandelion at home," he went on, and then used the same phrase as the mental patient—"I felt fine." "Last year we sold £1,100 worth of stuff from this garden," the head gardener of a great public institution told me, "beautiful stuff." "Do you provide the patients with it"? I asked. "Not likely!" he said. "I offered some to the steward, but he said, 'I can get stuff good enough for these patients at two-thirds that price.'" No chicane—an honest, if mistaken, transaction.

There are very good farmers in the House of Lords. They are of various parties; but they all unite in their agricultural policy. Here are two items of it, or fragments of them: "A greater production and consumption of protective foods must form the basis of any sound agricultural and health policy"; and, "We lay down the distinction between those commodities (e.g., wheat, meat, sugar-beet, etc.) of which we must produce certain quantities in order to ensure good husbandry, but the production of which we do not desire to expand beyond" that limit, and "milk, poultry products, fruit, vegetables, for which a large potential market is available, and which can and should be expanded to a considerable degree in the interests alike of agriculture and the national health."

They, the farmer Lords, have realized this great truth. Have we, in our profession, grasped and used this means of making "positive health"?—I am, etc.,

Holmes Chapel, Cheshire. LIONEL JAS. PICTON.

A Maternity Service Scheme

SIR,—Dame Louise McIlroy's interesting article on a maternity service scheme (Aug. 15, p. 184) contains a phrase which may produce a wrong impression.

In speaking of the position of pregnant women in the U.S.S.R., she says: "Women in employment get full pay before and after confinement, if off work." By law, pregnant women in the U.S.S.R. are *obliged* to take 35 days' leave before confinement and 28 days' after, on full pay. Many other provisions are made for women before and after confinement. For instance, pregnant women in industry are not allowed to work overtime or night shifts, and their occupation is changed to lighter work if their original work is considered unsuitable. They have various privileges, such as being entitled to board a bus or train before anyone else. Women who return to work after confinement and who wish to take their children with them can leave them in the factory crèche. Arrangements are made by which the mothers are given time off at regular intervals, without reduction in pay, so that they can breast-feed their children.—I am, etc.,

London, W.1. D. E. BUNBURY.

Obituary

PROFESSOR CLAIRMONT

Prof. G. GREY TURNER writes: The death of Prof. Paul Clairmont of Zurich at the age of 67 recalls a very delightful visit to Vienna in 1912, when he was the very capable first assistant in the clinic of the late Prof. Von Eisleberg. In that capacity he was responsible for a great deal of the work and proved himself a very enthusiastic second to his great chief. It was not long previously that he had devised and introduced the operation which is now known by his name for the treatment of recurrent dislocation of the shoulder-joint. I remember how skilfully he demonstrated the method on the cadaver one evening and the next morning carried out the operation on a patient whose shoulder had been dislocated no fewer than 23 times. In the surgical laboratory there was a lively discussion between Clairmont and Prof. Perthes of Tübingen, who was also a visitor. The aetiology of recurrent dislocation and the respective merits of the operative management were discussed with some ardour. The matter ended by Clairmont's inviting his friendly rival also to demonstrate his plan on the body. Those were great days and only to be recalled with a certain amount of nostalgia.

It was not very long afterwards that Clairmont was appointed professor in charge of the surgical clinic at Zurich, so that he came to occupy a Chair upon which Sauerbruch had added great lustre. In 1924, as a visitor to his new clinic, one saw much of his notable activities. I recall that he started operating at 7.30 each morning and that his lists were formidable. Like most Continental surgeons he was in no sense a specialist, and on that occasion we saw a great variety of work, yet after the operations this man of energy insisted on taking us on a tour of the wards before luncheon. Clairmont was probably then at the height of his activity and reputation, and a good many foreign students were attached to his clinic. His hospitality on that occasion was boundless, and among other things we enjoyed a delightful evening at his house, which was marked by a dinner party served on two floors. Again, in 1937, when 62 years of age, friends tell me that his energy seemed to be unabated; in fact it was almost alarming. He never seemed to tire and did some of the biggest surgical operations with great vigour. His work was mainly practical and individual, but a great many British visitors will remember with pleasure days spent in his clinic and with profitable results.

Many members of our profession will learn with regret of the sudden death on August 7 of Mr. R. W. CRAWFORD TREASURE of the Medical Insurance Agency. When the last war began, Mr. Treasure was engaged in a commercial career in India, and was a member of a Volunteer Artillery Battery in which he served throughout the war, obtaining the rank of major. After demobilization he returned to England, where his father, the late Dr. W. B. Crawford Treasure of Cardiff, was a well-known and popular member of the Central Council of the B.M.A. He then obtained a position on the staff of the Medical Insurance Agency, rising to be deputy manager under the late Mr. Adamthwaite, and assistant manager under his successor, Mr. A. N. Dixon (now in the R.A.F.). Since Sqdn. Leader Dixon rejoined the Forces Mr. Treasure had been acting manager in his stead. He had for many years dealt with the sometimes thorny problems of claims against underwriters or insurance companies by clients of the Agency in connexion with motor-car accidents, always with great courtesy to clients and keenness in defence of their interests. When he had, as sometimes happened, the invidious task of explaining to a doctor that his claim was less well founded than he supposed, he did it with tact and kindliness, if seldom with terseness. His personal contacts with members of the profession, which were very numerous, always left the impression of complete devotion to the interests of the insured as well as of straightforwardness, and this combination of qualities was undoubtedly appreciated both by the Agency and by its clients. Mr. Treasure, who was twice married, leaves a widow; also a son by his first wife.

Dr. A. C. D. TELFER, who died suddenly on August 19 at Walthamstow at the age of 46, had been in practice there for the past 20 years. He studied medicine at St. Bartholomew's Hospital, graduating L.M.S.S.R. and M.B., B.S.Lond. (Hons. Foren. Med.) in 1920. He was a very ardent though most cheerful worker and was keenly interested in the psychological side of medicine. Recently his energies had been devoted to evolving a scheme for the early and continued treatment of war neuroses, and he published tentative suggestions on those lines in the *Journal* of Feb. 28, 1942. His passing will be deeply mourned by patients and colleagues as well as by a wide circle of friends.

The Services

Prisoners of War.—War Subs. Capt. H. C. Allan, R A.M.C., Acting Surg. Cmdr H. L. Cleave, R.N , Capt. F. J Fish, R A.M.C., Surg. Lieut.-Cmdr W. D. Gunn, R.N., Temp Surg. Lieut. C. A. Jackson, R.N.V R., Capt G Lancaster, R.A M.C., War Subs Capt. D. R. Macaulay, R.A M.C., Temp Major K. A. Moore, R.A.M.C., Surg. Lieut.-Cmdr J. A Page, R N., Major E J. Pryn, R.A.M.C., Temp. Major H. L. Thornton, R A M.C., Surg Cmdr. R. W. H. Tinckner, R.N.V.R., Temp. Surg. Lieut. R G. S. Whitfield, R.N.V.R., Flying Officer R. J. S. Wilson, R.A F.V R.

Missing.—Lieut.-Col. J W. Malcolm, O.B.E., M.C., R.A.M.C.

Universities and Colleges

UNIVERSITY OF LONDON

Sir Girling Ball and Dr. A. M. H. Gray have been reappointed representatives of the Faculty of Medicine and Dr. H E. A. Boldero representative of the General Medical Schools in the Senate for the period 1942-6. The membership of Convocation of Major-General P. H. Mitchiner has been continued until May, 1943 The title of Professor Emeritus of Anatomy in the University of London has been conferred on Prof. J. E. S. Frazer following his retirement, owing to ill-health, in 1940 from the Chair of Anatomy at St. Mary's Hospital Medical School.

The degree of B Sc. (Econ) (with honours) has been granted to W. E. Roper Saunders, M.R.C.S, L.R C.P., D P H., D P A

An additional second examination for medical degrees for internal and external students will be held in December As a temporary measure during the period of the present shortage of medical practitioners, the length of the clinical course for the M.B, B.S. examination has been reduced from 36 months to 30 months. The matter is to be reconsidered during the third term of the session 1942-3. The examination for the Academic and External Diplomas in Clinical Pathology has been postponed from Oct, 1942, to Jan., 1943.

UNIVERSITY OF ABERDEEN

Sir John Boyd Orr, M.D., F.R.S, director of the Rowett Institute for Research in Animal Nutrition, has been appointed by the Aberdeen University Court to be Professor of Agriculture in the university He will continue as director of the Rowett Institute.

SOCIETY OF APOTHECARIES OF LONDON

At a Court of Assistants held at the Society's Hall on Aug. 18 Sir Stanley Woodwark, Master, and Dr. F. Gymer Parsons and Mr. V. Warren Low, Wardens, were re-elected for the ensuing year. The Court resolved to revive the pre-medical examination in chemistry, physics, and biology. The name of William Spencer Lewis was removed from the Register of Licentiates.

The following candidates have satisfied the examiners in the subjects indicated:

SURGERY—A G. S Bailey, D M Carnegie, J A Dryden, H Gottschalk, J M Hanson, G Jarratt, R. Powell, D S Jones, T. C Masson, F R. C. Palmer, S. Yaffie.

MEDICINE—C. A Anderson, G. Jarratt, M Leven, T. W. Renton, E. A. Williams, P L. McN. Armstrong, A. G. S. Bailey, M. V Matthew, F. A. Rutland

MIDWIFERY.—A. G. S Bailey, R. Gunewardena, M A. Hamdy, G. Jarratt, J A Dryden.

The diploma of the society was granted to C A Anderson, R Powell, R. Gunewardena, T W. Renton, G. Jarratt, P. L. McN. Armstrong, A. G. S. Bailey, and F A. Rutland

Medical News

The Council of Epsom College will in December next award a "France" pension of £30 per annum to a necessitous medical man, fully 55 years of age, who has been registered for five years, and who is in need of help. Forms of application may be had from the Secretary's Office, Epsom College, Surrey, and must be completed and returned by Oct. 19.

The Paddington Medical Society has arranged an informal reception to be held in the board room of St. Mary's Hospital (Praed Street entrance) on Sunday, Sept. 20, at 2.30 p m., to meet medical men and women in this country on war service from the U.S.A., the Dominions, and India, and to exchange views on matters of general medical interest. Those who wish to attend are asked to communicate with the honorary secretary of the society, Dr. L. Zeitline (16, Norfolk Place, Hyde Park, W.2) by Sept. 15 at the latest

The *Times* of Aug. 31 published a list of British refugees from the Far East who are on board the S.S. *Tatuta Maru*, which arrived at Lourenço Marques on Aug. 27. The Foreign Office, in supplying the list, stated that the names were furnished by the Swiss authorities. The following medical practitioners and members of their families are included: From Japan and Manchukuo, Dr. Dorothy Faulkner, Dr. and Mrs. Leggate, Dr. A. P. and Mrs. Littlewood, Dr. Jean M. McMinn, ? Dr. H. W. Y Taylor. From Swatow, Dr. S. L. Strange, Dr. and Mrs H. F. Wallace and two children. (The question mark in front of Dr. Taylor's name appears in the printed list.)

The Institución Cultural Española in Buenos Aires has established a laboratory for histological investigation in memory of Prof. Ramon y Cajal, to be directed by Prof. Hortega of Buenos Aires, a disciple of Ramon y Cajal.

A medical aid car, paid for by money raised by the sisters attached to the first-aid posts throughout the city, was handed over to the Lord Provost in the quadrangle of the City Chambers, Edinburgh, on August 31. The purpose of the car is to ensure that a doctor and nurse can be carried speedily to the scene of an air-raid incident, and have at hand the equipment for first aid, resuscitation of suffocated persons, and for minor emergency surgery. There are racks for two stretchers, so that any gravely injured person may be sent to hospital accompanied by a doctor or nurse, if need be. The car is to supplement, but not to replace, the official mobile first-aid units, and other Scottish cities and towns may be asked by the Department of Health for Scotland to adapt cars for similar purposes. Dr. W. G. Clark, Medical Officer of Health, acted as chairman at the ceremony. Lord Provost Darling paid a tribute to the Civil Defence services, which, he said, went from strength to strength. Although Edinburgh had not been subject to heavy bombardment, they had not been idle; they had trained and planned to make their service more and more competent.

A mobile resuscitation van, believed to be the only one of its kind in the country, and designed for use in maternity cases in peacetime as well as for emergency operations and blood transfusions in war, has been presented to Bradford by the Princess Royal on behalf of members of the women's section of Bradford and District British Legion, who raised the funds. The van is fitted for use as an emergency operating theatre, and contains an operating table, special "rocking" stretcher for artificial respiration, generous cupboards and lockers for instruments and sterile dressings, a special store of transfusion fluids, wash-basins, a sluice, microscope, electric blanket, a centrifuge, and other equipment.

The report and accounts of the Cassel Hospital for Functional Nervous Disorders for the year 1941 is issued from Ash Hall, Bucknall, Stoke-on-Trent, and includes a brief tribute to the memory of Dr. T. A. Ross, with a bibliography of his published works.

According to the last published return the Japanese death rate is 17.4 per 1,000 as compared with 10 or 11 in the United States, and the mortality from tuberculosis in Japan is 204 as compared with 45 per 100,000 in the United States.

Infant mortality in the United States per 1,000 live births has fallen from 51 in 1938 to 48 in 1939 and 46.4 in 1940, and in New York City from 38.3 to 37.1 and 34.8 respectively.

Dr. Fauconnet has succeeded the late Dr. Carrière as director of the International Office of Public Health in Paris.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the only large fluctuations from the preceding week in the notifications of infectious diseases were a drop of 894 for measles and of 94 for acute pneumonia, and a rise of 110 for whooping-cough. The higher incidence of whooping-cough was due mainly to the epidemic in London, where 141 cases, compared with 97 in the previous week, were recorded.

A decline in the notifications of measles was general throughout the country, especially in Lancashire, London, Middlesex, and Kent, where the cases were 124, 168, 109, and 70 fewer than in the previous week.

There was no large outbreak of dysentery during the week, the biggest county totals being those of London 17 cases and Berkshire (Wallingford R.D.) 8 cases.

In *Scotland* there were relatively large decreases in the incidence of measles, 49 cases, and acute pneumonia, 47 cases. The decline in measles was fairly general throughout the country, but the trend of pneumonia was mainly influenced by the returns of Glasgow, which showed a reduction of 30 cases. A rise of 25 cases of dysentery was reported, the principal outbreaks being those of Aberdeen Burgh 13, Dundee 13, Edinburgh 11, Glasgow 12.

The returns for *Eire* have been distorted by the inclusion in the present week of returns for a Dublin institution for the period from February to July. As a result of this the weekly total for whooping-cough is overstated by 122 cases, and diarrhoea and enteritis by 56 cases.

Returns for the Week Ending August 29

The notifications of infectious diseases in England and Wales for the week included the following: scarlet fever 1,455, whooping-cough 1,212, diphtheria 717, measles 3,165, acute pneumonia 352, cerebrospinal fever 66, dysentery 91, paratyphoid 11, typhoid 18.

No 33

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 22.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for. (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Doctors' Illnesses: Clinical Accounts Wanted

Dr. D. M. C. CHURCH (44, George Square, Edinburgh) writes: I wish to get accounts from medical men of illnesses of any sort from which they themselves are suffering or have suffered, and of which they have a clear recollection. This is a corner of clinical research which appears to have been little worked, and I have been impressed recently by the unusual slant it gives a clinical description. Particularly I should like to have the story of the onset of malignant disease: what first attracted attention, what was the psychological reaction, and so on. As regards diagnosis and treatment a criticism of these should be given. If there is response to this letter endeavour will be made to acknowledge the communication, which should, if possible, be typed. If the material obtained warrants publication in whole or in part, anonymity is promised.

Income Tax

Basis of Assessment

W. B. inquires to which year precisely a demand "for the year beginning April 6, 1941," relates.

*** In reply to this correspondent, the point to keep firmly in mind is that professional earnings are assessed for any particular year on the basis of the amount earned in the previous year. Consequently, tax payable "for the year beginning April 6, 1941," will be calculated on the amount of the profits for the year *to* that date (or to December 31, 1940, for instance, if that is the date to which the professional accounts are prepared), and when tax thereon has been paid the practitioner will have accounted for his liability up to April 5, 1942. There are some exceptions to the general rule, which are briefly explained in the printed notes accompanying the form of return. (If, as seems to be the case, W. B. cannot obtain a reply from the local inspector of taxes, he would be justified in complaining to the Chief Inspector of Taxes, Somerset House, W.C.2.)

First Two Years of Employment

R. W. began general practice work in January, 1941, at a salary of £600 per annum. How should he be assessed for the two years ending April 5, 1941, and April 5, 1942, respectively?

*** The statutory basis of assessment under Schedule E in such a case is the earnings of the current year for each of the first two years. R. W. is therefore chargeable to tax on £150 for 1940–1 and on £600 for 1941–2. (If the appointment terminated before April 5, 1942, he would of course be entitled to a reduction of the £600 to the amount earned after April 5, 1941.) The tax can be notified to the employer, and deducted over the period applicable to the year concerned.

LETTERS, NOTES, ETC.

Powdered Sulphanilamide for Throat Infection

Dr. GODFREY B. TAIT (Alloa) writes: Much literature has appeared on the subject of local application of sulphonamides. This, to my knowledge, has been restricted to surgery and dermatology. Apart from the trial of sulphanilamide snuffs for disinfection of the nose, I have seen no other mention of its local use in "medical" conditions. The fact that I am extremely intolerant to sulphanilamide taken by mouth led me to use it locally when I started to have a streptococcal tonsillitis. The powdered sulphanilamide was deposited on the tonsils, fauces, and palate by means of an insufflator. The result was highly successful. Pain and swelling disappeared in a day and a half. I have since tried this method with intelligent patients and results have been uniformly good, the condition clearing very rapidly. To be successful the insufflation must be carried out very frequently, at least half-hourly, for the throat secretions soon wash the visible powder away. For this reason and because of the expense of an insufflator the method cannot have a wide application in general practice, but for the doctor who feels a "sore throat coming on" it is the ideal treatment. The powder I have used was 30% sulphapyridine in mag. carb. lev. I have used this method for a year now and have seen no bad results.

Ambulances for Home Guard

Dr. W. C. V. BROTHWOOD (Medical Adviser, No. 2 Zone, Home Guard) writes: I have read the account of the "Duerr-Moir" light trailer ambulance (Aug. 8, p. 160). No doubt it will have been read with great interest by other Home Guard medical officers and particularly those in rural areas. It is the duty of these officers to make arrangements for the transport of casualties from defended localities to collecting posts, whence they are removed by Civil Defence ambulances. Home Guard units at present are not provided with ambulances. Under existing arrangements, therefore, casualties have to be carried by hand on stretchers from the defended localities to the collecting posts. Efforts have been made to keep down the "carry" to a minimum, but in rural areas even a small "carry" requires much physical effort, and the provision for such areas of an ambulance of the "Duerr-Moir" type, which can be used as a hand ambulance, would be a boon. It is clear that much thought has been devoted to its construction.

Dr. K. W. MACKIE (Southampton) writes: The Duerr-Moir ambulance trailer appears to be most suitable for country districts where the present ambulance service is inadequate. I understand that the ambulances are not in production yet. I sincerely trust that their production will not long be delayed and that those in authority may be persuaded to adopt the ambulance for use in Home Guard units.

Corrigendum

Dr. J. P. MCGOWAN points out an important omission in the schematic representation of red blood cell changes in his letter at page 257 of our issue for Aug. 29. An arrow should have appeared *pointing up from the macroblast to the normoblast*, since he contends that the normoblast does not develop into the macroblast.

MEDICINE 100 YEARS AGO

Three advertisements appearing in the *Provincial Medical Journal*, September 10, 1842:

THE PARENTS of a YOUTH, about seventeen years of age, are desirous of placing him as DISPENSING ASSISTANT with a Medical Man. He has served part of his time with a Chemist, and is, therefore, competent to undertake such a situation. An annual remuneration of £10 will be required. Address, A. B., Messrs. Drew, Heyward, and Co., Druggists, Bush-lane, London.

* * *

WANTED, by a Surgeon, residing in a pleasant and healthful situation in the country, TWO well-educated YOUNG GENTLEMEN as HOUSE PUPILS, who will enjoy peculiar advantages in the acquirement of a practical knowledge of their profession, the Advertiser having the Surgical charge of ten large Collieries, where casualties of the most serious nature occur, in the treatment of which his Pupils participate. Great attention will be given to the domestic comfort of the Pupil, and he will be stimulated to the improvement of his classical and general attainments. The Advertiser, being a licensed Teacher of Anatomy, will, as often as opportunities present, give Private Instruction in Morbid and General Anatomy. Apply to Mr. William Morrison, Pelaw House, Chester-le-Street, Durham.

* * *

SALE BY AUCTION OF MR. LANGSTAFF'S MUSEUM

MESSRS. I. C. and S. STEVENS have the honor to announce they will SELL BY AUCTION, at their Great Room, 38, King-street, Covent-garden, on Thursday, the 22nd of September, and six following days (Sunday excepted), at Twelve o'Clock, the very extensive and valuable MUSEUM of MORBID, HUMAN, and COMPARATIVE ANATOMY, formed by G. Langstaff, Esq., during a period of upwards of thirty years, with indefatigable labor, and at a very great cost. May be viewed three days prior to the Sale, and Catalogues (1s. each) had of Messrs. I. C. and S. Stevens, 38, King-street, Covent-Garden.

N.B.—A Catalogue *raisonnée* of the Collection is Published by Churchill, Princes-street, Soho (price 10s.).

ESTIMATION OF HAEMOGLOBIN BY THE ALKALINE HAEMATIN METHOD

BY

J. W. CLEGG, M.R.C.S., L.R.C.P., D.C.P.Lond.

Area Clinical Pathologist (E.M.S.) at the Royal Infirmary, Blackburn, Lancs; formerly Assistant in Clinical Pathology, British Postgraduate Medical School

AND

E. J. KING, M.A., Ph.D.

Reader in Pathological Chemistry, University of London

(From the British Postgraduate Medical School and the E.M.S. Pathological Services, Sector VI)

Haemoglobinometry has at present two chief functions—first, the detection of diseases characterized by deficiency or excess of haemoglobin; secondly, the study of changes in haemoglobin concentration caused by loss or gain of plasma. For both purposes it is desirable that the method employed should estimate the concentration of all the forms of haem-pigment circulating in the blood. Ammundsen (1939, 1941) has shown that under modern conditions a normal adult may have from 2 to 12% of his total haemoglobin circulating in an inactive form. The inactive fraction is chiefly composed of carboxyhaemoglobin, methaemoglobin, and sulphaemoglobin. Drugs of the sulphonamide class often increase the proportion of inactive haemoglobin in patients receiving this form of treatment. Most methods of estimating haemoglobin are standardized by reference to determinations of the oxygen-carrying power of blood. These yield valuable information concerning one important function of the blood, but they may provide a false picture of the pigment metabolism, since they take no account of inactive haemoglobin which may be capable of regeneration to the active form. They may imply the presence of anaemia where none exists. Several methods of estimation are in general use, and it is pertinent to inquire not only into the accuracy of each but also if total pigment or merely active haemoglobin is being measured.

The Haldane method enjoys a wide popularity, yet, being based on the gas (CO)-carrying power of blood, it may not measure total pigment. Samples of blood are frequently encountered in which the colour is not comparable with the standard; this is probably due to the presence of a large amount of inactive haemoglobin which is not convertible to carboxyhaemoglobin. The standards available commercially are often unreliable and may quickly fade. In addition the method requires a source of carbon monoxide.

There are several acid haematin methods in use, of which the most familiar are the Sahli and Newcomer. Several disadvantages are common to them all. The colour developed by the test does not quickly reach a maximum; while most of it develops in the first 30 or 40 minutes, the greatest optical density is not reached for from 24 to 36 hours, and the velocity of the colour reaction is not constant. Some observers claim the colours are not easily matched and that there is a high degree of personal error: according to Heilmeyer and Von Mutius (1938) this may be as high as ± 10%. Wu (1922) has shown that the colour developed depends upon the concentration of protein and lipoid in the test; and, since acid haematin is insoluble and exists as a colloid suspension protected by the protein present, there is often turbidity or actual precipitation.

The pyridine haemochromagen method of Roets (1940) [cf. Rimington, 1942] depends on the following principle. Haemoglobin in the sample is converted by sodium hydroxide, pyridine, and sodium hydrosulphite into pyridine haemochromagen. The standard is crystalline haemin, which is converted to the haemochromagen with the same reagents. The two solutions are compared colorimetrically and the concentration of haemoglobin in the test is calculated on the assumption that each milligramme of iron in the haemin standard is exactly the equivalent of a milligramme of haemoglobin iron in the test. This method has the advantage of a standard which is readily reproducible, and in addition it measures total pigment; but most pathologists would probably agree that pyridine, because of its extremely objectionable odour, is an unsuitable reagent for use in a routine clinical laboratory.

Recently we have been searching for some method of haemoglobin estimation which fulfils the following criteria. It must measure total pigment with a reasonable degree of accuracy and yet be simple enough to be employed in a laboratory where many determinations are performed daily. Measurement must be in terms of some simple easily reproducible standard so that the results at one laboratory may be directly comparable with those obtained in another. This standard must be either haemoglobin or some other substance with constant properties which may be referred to haemoglobin. From a review of the literature we decided that the most likely procedure was the alkaline haematin method of Wu (1922), which is recommended by Peters and van Slyke (1932). Wu found that the acid haematin method of Cohen and Smith (1919), the CO method of Palmer (1918), the methaemoglobin method of McEllroy (1920), and the cyanhaemoglobin method of Stadie (1920) gave divergent results with sheep's blood; but that if the test solutions were all rendered alkaline before the colorimetric readings were made the differences largely disappeared. The acid haematin method applied to solutions of pure haemoglobin gave lower results than those obtained when plasma was added. The errors increased with increasing amounts of plasma, but were not proportional to the plasma present. With solutions of washed red cells the reverse was the case: added plasma decreased the apparent observed concentration of haemoglobin. These extraordinary effects, probably due to the colloidal nature of haematin in the acid medium and of proteins and fats from the plasma, were abolished by the addition of excess sodium hydroxide to the test solutions. Haematin exists in true solution in alkaline solutions of pH 10 and over, and plasma proteins and fat are likewise much better dissolved by alkali than by acid. The presence of variable amounts of the abnormal forms of haemoglobin (CO-, met-, cyan-), moreover, exerted a pronounced effect on the acid haematin method, but no effect when the solutions were made alkaline, the same amount of alkaline haematin being produced from any form of haemoglobin or from mixtures of them. The alkaline haematin method of Wu, then, appeared to satisfy our criteria of reasonable accuracy, of simplicity, and of measuring all forms of haemoglobin.

The majority of the standards in use for the different methods of haemoglobinometry are prepared from blood. This is a grave disadvantage, as the blood needs careful standardization by the oxygen capacity method, a procedure which requires elaborate apparatus and a skilled technique and which is difficult for those who are not experienced in gas analyses. The standards prepared from blood are, moreover, not easily preserved, and frequent restandardization is necessary. Because of these difficulties there has been a wide-spread adoption of coloured glass standards, but these have proved unsatisfactory because of lack of uniformity and of the failure to give an equally good match of the haemoglobin colours in light from different sources. The alkaline haematin method carries the great advantage that a simple reproducible standard can be prepared from crystalline haemin, a substance which is easy to prepare and which can be weighed out in equal amount and dissolved in soda by any worker to give standards of identical colour value.

Haematin Standards

Thirteen samples of crystalline haemin have been prepared by slightly different methods from ox and human bloods.[1] The iron content of each sample was determined and the results are shown in Table I. Solutions of alkaline haematin containing approximately 10 mg. of haemin per 100 c.cm. were prepared and the specific extinction coefficients of the solutions measured. The mean of the 13 samples is 0.769, with a standard deviation of 0.009 and a coefficient of variation of 1.18%. Three other samples, one prepared in bulk by B.D.H. and two kindly supplied by Dr. R. G. Macfarlane of Oxford, agree closely with the results in the table. These solutions, which have remained stable for over six months, obey the Beer-Lambert law. Clearly when alkaline haematin is prepared from crystalline haemin the intensity of the colour developed is proportional to the concentration of iron in the sample.

Table I.—*Specific Extinction Coefficients of Various Preparations of Haemin**

‡ Determined in photo-electric colorimeter (King, 1942), Chance green filter. The extinction coefficients re-determined on these same solutions 6 months after their preparation were identical with those shown.

Alkaline Haematin Method Applied to Blood

When adult human blood is added to decinormal sodium hydroxide, a brown colour is quickly developed which on spectroscopic examination contains the specific absorption band of alkaline haematin (607 mμ). Blood taken from infants develops this colour much more slowly owing to the fact that the foetal type of haemoglobin is more resistant to alkaline denaturation. Brinkman and Jonxis (1935) have shown that the foetal type of haemoglobin steadily diminishes after birth and is absent at 7 months; at about 3 years another type of alkali-resistant haemoglobin appears, and persists throughout life. This adult resistant haemoglobin occurs only in small concentrations and the main bulk of adult haemoglobin has little resistance to alkali. The rate of alkali denaturation of all forms is markedly accelerated by increasing the pH and the temperature. We have investigated the rate at which alkali denaturation becomes complete in samples containing varying proportions of resistant and inactive haemoglobin.

If a 1 in 100 dilution of umbilical cord blood in N/10 soda is made, the solution remains bright pink, with the absorption bands of oxyhaemoglobin clearly visible for some hours at room temperature. With brief heating the colour change is dramatic, and the oxyhaemoglobin bands are replaced by those of alkaline haematin. The effect of heat was studied by making a 1 in 100 dilution of umbilical cord blood and placing it in a boiling-water bath. Aliquots were removed at various intervals and promptly cooled under the tap before being compared in a colorimeter with a standard alkaline haematin solution. It was found that the colour reaction, often complete after 2 minutes in the bath, was invariably so after 5 minutes. For a further short and variable time the colour remained constant, but turbidity developed later, giving an apparent increase in colour. No significant turbidity was detected after only 5 minutes in the bath (Table II).

Table II.—*Effect of Heat on Alkali Denaturation of Foetal Type Haemoglobin*

* Still pink. † Clear brown ‡ Turbidity.

The figures represent the extinctions E read in the King (1942) photo-electric colorimeter, Chance green filter.

Many observations were made on hospital patients to determine if any appreciable concentration of resistant haemoglobin might be encountered. 0.05 c.cm. of blood was added to 5 c.cm. of N/10 soda. After this unheated solution had been compared with a standard solution it was allowed to stand overnight, when the comparison was repeated. In many cases there was no significant difference between the two observations, but in some adults and all infants the overnight reading was significantly lower than the initial reading—i.e., the change from pink to brown was not complete in the few minutes before the first reading.

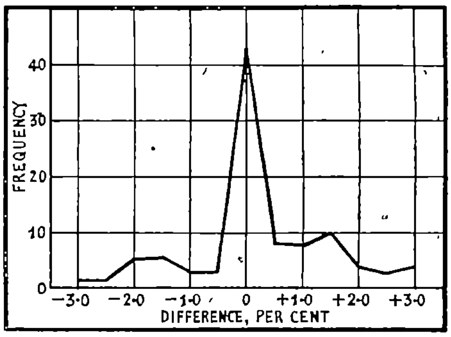

Fig. 1.—Difference in colour of blood in N/10 NaOH produced by heating for 5 minutes and by standing overnight at room temperature.

The effect of heating all specimens was then studied, 0.1 c.cm. of blood being added to 10 c.cm. of N/10 soda and the specimen divided. One-half of each test was placed in the boiling-water bath for exactly 5 minutes, cooled under the tap, and compared with the standard haematin solution. The other half was allowed to stand overnight and also compared with the standard. Fig. 1 is a distribution curve of 100 consecutive observations on 96 patients and 4 specimens of umbilical cord blood. No observation falls outside the limits of 3% of the same reading, 91% of cases are within 2%, and in 43% of cases the observations are identical. The mean overnight reading is 100.285 of the 5-minute reading, and the standard deviation is 1.72.

---

[1] The methods of preparation and of iron analysis are published elsewhere (Delory, 1942).

A comparison was next made of a series of alkaline haematin values produced by 4–5-minute heating in sodium hydroxide with those developed by Wu's procedure—i.e., a 40-minute treatment of the blood with N/10 hydrochloric acid at room temperature followed by the addition of excess sodium hydroxide. Table III shows the close agreement of the two alkaline haematin methods, and the discrepancies between them and the acid haematin procedure.

* 0 05 c.cm. blood in 5 c.cm. N/10 NaOH, heated 5 minutes.

† 0·05 c.cm. blood in 4 c.cm. N/10 HCl, let stand 40 minutes, made alkaline with 1 c.cm. N/1 NaOH.

From these experiments it seems clear that the same final alkaline haematin colour is developed equally well either by treating the blood directly with soda and heating or allowing to stand at room temperature for many hours, or by an initial treatment to convert the haemoglobin into acid haematin followed by the addition of soda to render it alkaline.

To study the effect of inactive haemoglobin it is necessary to subject the sample to considerable manipulation with increased opportunity for introducing sampling errors. To reduce these as far as possible normal blood was lysed with water and filtered, the resulting solutions being much easier to handle than whole blood. Table IV indicates the steps taken to convert the haemoglobin into inactive forms, and also shows that they are quantitatively converted to alkaline haematin by heating for 5 minutes in the water-bath. This experiment confirms the finding of Wu, that the different forms of haemoglobin are quantitatively determined when estimated by the alkaline haematin method.

TABLE IV.—*Colour Produced by Different Forms of Haemoglobin when Estimated by the Alkaline Haematin Method*

Solution	Untreated	As COHb (gassed for 30 min.)	As Sulph-Hb (H_2S passed for 10 min)	As Met-Hb (Treated with Pot. Ferricyanide)
1	0·168	0·162	0·171	0·162

5	0·346	0·336	0·347	0·339

(Figures represent extinctions E, photo-electric colorimeter, Chance green light filter.)

Likewise, the addition of plasma either to the haemin standard or to tests prepared from blood had little or no effect. Plasma added in amount equal to the volume of blood taken—i.e., 0.05 c.cm. in 5 c.cm. of soda—caused no measurable change in many cases, and in others the change was of the order of 1% increase. The most pronounced effect observed was a 2% increase in optical density due to adding a turbid specimen of plasma.

Relation of Colours Produced from Haemin and from Haemoglobin in Sodium Hydroxide

From theoretical considerations it now seemed possible to equate solutions of alkaline haematin derived from haemin and from blood on the assumption that one milligramme of iron in the haemin standard would be equivalent to one milligramme of iron in the haemoglobin test. Attempts to apply this assumption to the clinical estimation of haemoglobin showed that bloods examined in this way yielded results by the alkaline haematin method which were higher than could be justified either by the clinical condition of the patient or by examination of the stained blood film. In a small series of hospital cases venous blood samples were analysed for haemoglobin by the alkaline haematin procedure and for oxygen capacity with the van Slyke manometric apparatus by Dr. J. McMichael. The results obtained by the haematin method were uniformly about 30% higher than the oxygen capacity—a far greater difference than could be accounted for by the presence of small amounts of inactive haemoglobin in the normal blood samples investigated.

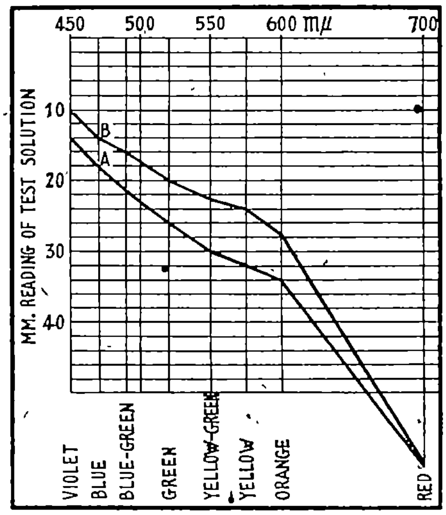

FIG. 2.—Light-absorption curves of haemin in sodium hydroxide (A) and of haemoglobin heated in sodium hydroxide (B); Ilford spectral filters, neutral grey screen, Duboscq colorimeter.

The colour of alkaline haematin derived from blood had been assumed to be identical with that derived from haemin, but these results suggested that this was not the case. Although the colours were similar to the unaided eye, and had the same broad band at 606 to 608 mμ when viewed in the Hartridge reversion spectroscope, they showed a slight dissimilarity in absorption in the red. Solutions derived from each source were examined in a colorimeter against a neutral grey screen, using a range of light filters covering the visual spectrum. The absorption curves are plotted from these data in Fig. 2, which indicates that the colours differ slightly in the red portion of the visual spectrum.

Several samples of human haemoglobin were then prepared by precipitation with alcohol as described by Delory (1942). By this method large yields of dried human haemoglobin were readily obtained in a semi-pure state. An iron analysis of quantities of about 1 g. was performed in duplicate on each sample. As in the case of haemin, solutions of alkaline haematin were prepared by dissolving the haemoglobin in N/10 soda. The extinction coefficient was measured and the absorption curve studied. This was found to agree with that derived from blood and to differ in the same way from that of haemin. The solutions were compared with solutions of haemin in N/10 soda and the ratio of colour intensity per mg. of iron in each solution calculated. In each case this ratio was found to be close to the mean of 1.32 for the five samples (Table VI).

TABLE VI.—*Colour of Various Haemoglobin Preparations*

Haemoglobin Preparation No.	% of Iron	Es*	Hb/Haemin Colour Ratio†
1 (human)	0·262	1·03	1 29
2 „	0·284	1 00	1·32
3 „	0·278	0·97	1·33
4 „	0·284	0·98	1·32
5 (ox)	0·249	1 00	1·33

* Es = specific extinction coefficients for 1 mg. haemoglobin Fe/100 c.cm. Photo-electric colorimeter, Chance green filter.

† Colour of haemoglobin solutions against a single haemin standard.

It appears, therefore, that although the brown colours produced in sodium hydroxide from blood and from crystalline haemin are seemingly the same on visual inspection and are similar over most of the visual spectrum, they are not in fact identical. There is a quantitative discrepancy of approximately 30% and a slight qualitative difference. The chemical reasons for the discrepancy are beyond the scope of this paper; suffice it to say that it can be adequately explained by the fact that the alkaline haematin solutions derived from haemoglobin and blood contain both haematin and globin, whereas that prepared from haemin contains only haematin and no globin. Haemin, then, cannot be used as a theoretical standard in the sense that four molecules of haemin should give the same colour as one molecule of haemoglobin. But it can be employed perfectly satisfactorily as an artificial standard. The colours produced by haemin and haemoglobin in soda are similar to the eye in any light,* and in green light they are easily and accurately matched and there is a constant ratio of colour intensity by whatever means the reading is made.

Methods for the Determination of Haemoglobin by the Alkaline Haematin Procedure

The brown colour of blood in sodium hydroxide solution is compared with that of a solution of crystalline haemin of known iron content.

Method 1.—0.05 c.cm. of blood is diluted to 5 c.cm. with N/10 NaOH, heated in a boiling-water bath for 4 to 5 minutes, cooled, and read against the haemin standard in a suitable colorimeter (Duboscq, photo-electric, etc.), using a green light filter.

Method 2 (Method of Wu; cf. Peters and van Slyke, 1932).—0.05 c.cm. of blood is treated with 4 c.cm. of N/10 HCl, left at room temperature for 40 minutes, and then diluted to 5 c.cm. with N/1 NaOH.

Standard.—The haemin-iron equivalents of the "100% normal" standards are shown in Table VII. An amount of haemin of known iron content, which is the equivalent of the desired standard, is accurately weighed and dissolved in 1 litre of N/10 NaOH. This solution should be preserved in a glass-stoppered bottle in a cool dark place. Kept under these conditions our standards have remained unaltered for 9 months.

Authorities differ as to the percentage of haemoglobin in blood which they regard as a normal figure. The three most commonly used are given in Table VII. There is an increasing body of evidence to show that Haldane's (1900) figure of 13.8 g. of haemoglobin is too low and that the Haden (1922) value of 15.6 g. per 100 c.cm. (20.9 c.cm. O_2) is a more normal figure (cf. Peters and van Slyke, 1932; Wardlaw, 1941). This is the figure we have used and which has seemed adequately to represent our normal healthy cases; it has given colour indices averaging unity for healthy persons and treated anaemias.

TABLE VII.—*Concentrations of "Normal" Blood Standards*

	Haldane	Haden	Sahli
g. haemoglobin/100 c.cm.	13·8	15·6	17·2
O_2 capacity (c.cm./100 c cm.)	18 5	20·9	23 0
mg. Fe/100 c.cm.	46 2	52 2	57 6
Alkaline haematin equivalents. mg. Fe/100 c cm * (i.e., haemoglobin Fe × $\frac{1.3}{100}$)	0·60	0·68	0·75
Pure haemin, 8·57% Fe (mg per litre)*	70·0	79·4	87·5

* Which give the same colour as blood diluted 1 in 100 in N/10 NaOH.

The alkaline haematin standard we use for routine is weaker than the "100%" standards. It contains an amount of haemin representing 0.45 mg. of iron. This solution matches any haemoglobin solution or blood containing 10.3 g. of haemoglobin per 100 c.cm. when treated with sodium hydroxide to give a dilution of 1 in 100. This standard was chosen because it is close to the average of the concentrations most often encountered in hospital practice. Its relation to the "normal blood" standards is shown in Table VIII. Haemin standards of "100% normal" may of course be used. The figures for these are given in Table VII. The method has now been in use for several months and has proved most satisfactory. Where many determinations are undertaken it is more rapid and more accurate than other methods we have used.

TABLE VIII—*Alkaline Haematin Standard for Routine Use with Duboscq and Photo-electric Colorimeters*

52.5 mg. of pure haemin (or an equivalent amount of other haemin of known Fe content) is dissolved in 1 litre of N/10 NaOH. This solution contains 0 45 mg. Fe/100 c.cm. and is equal in colour to:

75% of Haldane normal
66% of Haden „
60% of Sahli „

when blood is diluted 1 in 100 in NaOH

Approximate Methods

With the Lovibond Comparator.—Through the co-operation of Mr. G. S. Fawcett a Lovibond disk has been prepared to match the alkaline haematin colours. The values are spaced at 10% of the Haden normal—i.e., at differences of 1.56 g. haemoglobin per 100 c.cm. The blood is treated by either of the above procedures, the test-tube is placed in the Lovibond comparator, and the disk is rotated until a colour match is obtained. By careful comparison it is possible to gauge colours intermediate between those in the disk and hence to read the haemoglobin to within about 5%.

With the Hawksley Dilution Colorimeter.—The small dilution haemoglobinometer supplied by Messrs. Hawksley for the Sahli method is easily adapted by the substitution of the coloured glass standard by a tube of alkaline haematin solution (equal to 100% of normal—e.g., Haden). 0.02 c.cm. of blood is added to a little N/10 soda in a calibrated dilution-tube; the mixture is warmed until it is of a clear light-brown colour, and is then diluted by the dropwise addition of N/10 NaOH, with mixing, until a colour match is obtained. The percentage is read from the scale on the test-tube. If this method is employed care should be taken to ensure that the tubes used are properly calibrated and of the same diameter.

---

* The slight qualitative difference in the colours may be apparent if they are viewed through too great a depth of solution Thus a "100%" blood and the standard will appear identical in 1/4-inch dilution-tubes, but the colours will appear slightly different in wide test-tubes. On the other hand more dilute solutions of haemin and haemoglobin appear identical even when viewed through wide tubes.

Summary and Conclusions

The haem-pigments circulating in the blood may be divided into an active fraction, reduced and oxyhaemoglobin, and an inactive fraction chiefly carboxyhaemoglobin and methaemoglobin. A satisfactory method for estimating haemoglobin should measure both fractions.

The Haldane and acid haematin methods may not measure total pigment with the degree of accuracy desirable. Commercial standards are often unreliable and may fade. The pyridine haemochromagen method is rejected because of the objectionable nature of the reagents employed.

Criteria of a satisfactory method are described. These include the measurement of total pigment, reasonable accuracy, simplicity, the use of non-toxic reagents, and some permanent easily reproducible standard.

The alkaline haematin method of Wu eliminates errors which arise in the acid haematin procedure due to lipids, the colloidal nature of acid haematin, and the presence of inactive haemoglobin. Alkaline haematin has the advantage of being a true solution and is easily prepared both from haemoglobin and from crystalline haemin. Haemin is easy to prepare in a pure state from haemoglobin, and its iron content may be estimated with accuracy. Thus it appeared to satisfy our criteria for a suitable standard, and was investigated for this purpose.

Sixteen samples of crystalline haemin were prepared from ox and human bloods and the iron content of each determined. Solutions of alkaline haematin were prepared from each sample. The specific extinction coefficients were found to agree closely. The intensity of colour was proportional to the concentration of haemin iron, and impurities failed to influence the colour.

Several forms of haemoglobin occur in normal blood, some of which are resistant to alkali denaturation. Whatever the proportion of alkali-resistant haemoglobin in a blood sample, if a 1 in 100 dilution in decinormal soda is prepared and placed in a boiling-water bath for five minutes all the haemoglobin is converted into alkaline haematin.

Similar treatment converts all inactive forms of haemoglobin into alkaline haematin. The colour developed is not significantly influenced by the amount of lipoid or plasma in the sample.

Determinations of haemoglobin in blood samples based on the assumption that 1 mg. haemin iron in the standard was equivalent to 1 mg. haemoglobin iron in the test yielded results uniformly about 30% higher than determinations based on the oxygen-carrying power of the same sample. It was then found that solutions prepared from haemin and blood gave colours whose absorption curves differed slightly in the red portion of the spectrum.

Samples of human and ox haemoglobin were prepared and their iron content determined. Solutions of alkaline haematin were prepared from each sample and their specific extinction coefficients and absorption curves determined. The curves derived from the haemoglobin solutions were identical with that from blood, and the colour produced was 30% higher than would be anticipated from the iron content, when compared with haemin standards.

Thus haemin is not a theoretical standard in the sense that four molecules of haemin should give the same colour as one molecule of haemoglobin; but it can be employed satisfactorily as an artificial standard. The colours of the solutions are almost identical in the concentrations used for the test, and are matched with ease and accuracy. The standard appears to be unchanged during several months.

Details of methods for the estimation of total haemoglobin using haemin as a standard are given, together with instructions for the preparation of standard solutions equivalent to 100% of the Haldane, Sahli, and Haden scales.

We have employed this method for many months and have found it to give excellent results. Where many determinations are made daily it is quicker and more reliable than other methods we have used.

Our thanks are due to Dr. R. G. Macfarlane of Oxford and Dr. J. M. Peterson of Cardiff, who have carried out independent investigations of the alkaline haematin method, for helpful discussions and advice; to Mr. G. E. Delory for his invaluable assistance with the iron analyses; to Dr. J. McMichael for the estimations of O_2 capacity; to Mr. G. L. Widd for his assistance in comparing the alkaline and acid haematin methods; and to Dr. G. A. D. Haslewood for valuable advice.

LOUSE-BORNE TYPHUS FEVER

BY

Capt. C. DONALD, R.A.M.C.

AND

Capt. P. B. BARKER, R.A.M.C.

(*From a Prison Camp in Germany*)

The articles on this subject that appeared in the *British Medical Journal* of Dec. 6 and 20, 1941, have induced us to record our observations on a series of 21 cases occurring in a prison camp in Germany, of which 3 (14.28%) were fatal; 16 (76.18%) arose in men employed in handling clothing at the camp disinfector. In only 2 cases was it possible to determine the incubation period, and this was in accordance with the usual period of 12 to 14 days.

Onset

The illness was in some cases ushered in by severe frontal headaches, shivering, occasionally epistaxis, soreness of the throat, and thirst, followed by a general feverish feeling, like influenza. In milder cases, on the other hand, the patients felt quite well during the first 3 or 4 days in spite of their temperature being in the region of 102° F.

One patient gave a history of an attack of influenza for one day. He felt better the next day, but was cold and shivery; on the fourth day he suddenly developed acute abdominal pain, vomited twice, and was admitted to hospital as a case of acute appendicitis. His temperature was 102.2°, and his pulse 100; his urine contained nothing abnormal. A laparotomy was performed and the next morning his temperature and pulse fell to normal, but the same evening they rose to 102.9° and 112 per minute respectively, and remained about this level. On the third day after his operation the rash appeared—i.e., 6 days after his initial attack of influenza.

General Appearance immediately before Occurrence of Rash.—The conjunctival vessels were injected and the eyes assumed a heavy appearance reminiscent of measles without photophobia and lacrimation. The face was flushed and a dusky tinge or distinct cyanosis was present in the skin. The tongue was dry and thickly coated with white or brownish-white fur. Sordes of the mouth was very marked until frequent cleansing was adopted. The facial expression was worried, with a continual frown which was aggravated by questioning or outside interference. Speech was sluggish, and the patients appeared to have difficulty in expressing themselves. In some cases there was delirium immediately before the appearance of the rash, and all became increasingly drowsy. Acute dyspnoea usually occurred towards the end of this phase, and was suggestive of bronchopneumonia with only a few crepitations in the lungs.

The Rash: Character and Distribution

The rash appeared on the average on the sixth day; the shortest period was 5 days and the longest 10. It consisted of pink papulo-macules which later became bluish-red and slaty-blue in colour. It first appeared on the shoulder areas, back and front, especially in the neighbourhood of the axillary folds, on the upper abdomen, and on the flanks, and later it showed on the rest of the trunk and the limbs. It was especially prominent on the forearms, the backs of the hands, and the dorsal surfaces of the feet, and was to be clearly seen on the thenar eminences of the hands and on the medial aspects of the soles of the feet. In 4 (19%) cases the rash appeared on the frontal and temporal aspects of the face. As the macules started to fade subcuticular mottling made its appearance and persisted for about 4 weeks. In 9 (42.8%) cases the rash became petechial 2 or 3 days after the appearance of the macules, and involved the same areas. In one case the petechiae were extremely profuse and generalized; the mucous membrane of the mouth was involved and there was a large subconjunctival haemorrhage. In some cases the petechiae became confluent, over the pressure areas of the shoulders, heels, and sacrum, to form areas of ecchymosis. Later, in spite of precautions, some of these areas formed deep-seated gangrenous bed-sores which healed very slowly (one remained incompletely healed after 6 months). In cases in which the petechial rash appeared it was noticed that the illness was much more severe but not appreciably altered in duration.

Fine branny desquamation started towards the end of the third week from all areas in which the rash appeared, and included the face only in cases with a facial rash. Coarse desquamation occurred from the soles of the feet at this time. The desquamation lasted for about 2 weeks. In 5 (23.8%) cases there was no rash, and in those cases the illness was much milder.

The Fever

The fever proper lasted on an average 17 days. It was of a continuous type, between 100.4° and 103.2° F. (axillary). The maximum temperature recorded was 104.7°. The pulse rate was proportionate to the temperature on the whole, but at times it was disproportionately high. The pulse was easily compressible throughout. The respiration rate was markedly increased, and generally fell a day or two before lysis occurred. The fever tended to end by lysis over 3 to 4 days.

In 4 cases a sudden crisis followed by a rise of temperature in 24 hours, which was sustained over 3 to 4 days, did not prove fatal.

Observation of Patients during Febrile Stage.—During the first week of the fever the drowsy-stuporous condition increased daily. It became more difficult to rouse the patients; they were very restless, slept little, and their resentment of interference of any kind became more marked. Speech became more hesitant and incoherent; low muttering delirious bouts were frequent, and towards the end of the week the patients were semi-comatose. The duskiness and cyanosis of the skin increased in intensity and the respiration became more laboured. The tongue remained dry and furred, and it was difficult to get patients to drink although they complained of thirst. In the second week they passed into a state of coma vigil, in which they lay with open eyes, taking no notice of their surroundings although they still resented interference. At this phase the lips and the tongue were very tremulous, and the latter was difficult to protrude, this being done in a very slow jerky manner. In some cases the tongue appeared to be diminished in size and in 2 cases it was definitely shrivelled and almost black. The patients were becoming progressively more prostrate and their mental state was seldom lucid. Towards the end of the second week they seemed brighter, the tongue became moist, began to clean from the tip and edges, and was protruded more easily and less jerkily. The cyanotic tinge started to disappear and the respiration rate began to fall. The patients then had short periods of mental clarity during which they would ask to micturate, whereas they had previously been incontinent. During the first half of the third week the temperature and pulse rate fell by lysis and there was a marked day-to-day improvement in their condition. There was no abrupt passage from the stage of nervous excitement to that of defervescence. After the defervescence the patients were very emotional; they continued to have bouts of delirium and transient delusions, and were disinterested in and unnoticing of their surroundings and fellow patients until convalescence was well established.

Systemic Manifestations

Alimentary System.—Only in one case was the rash seen on the buccal mucous membrane, and there were no cases of parotitis. The fauces were slightly injected at the onset of the illness. Nausea was frequently complained of early, and vomiting was met with occasionally. Constipation was the general rule, but in 3 cases diarrhoea occurred at the end of the first week. Faecal incontinence was not uncommon during the second week. Abdominal pain occurred, and was so severe in one case that a laparotomy was performed (see above).

In 4 other cases suprapubic pain was associated with difficulty and pain on passing urine.

Respiratory System.—Marked dyspnoea with stertorous breathing and employment of the alae nasi occurred in all cases, and there was a short period of Cheyne-Stokes respiration just before the defervescence. There were 2 cases very suggestive of bronchopneumonia, but the only signs elicited in the others were a few isolated crepitations.

Cardiovascular System.—The pulse was easily compressible throughout the febrile stage, and one case exhibited pulsus paradoxus. The heart sounds became weaker as prostration became more marked, but there was no cardiac enlargement, no murmurs were detected, and no oedema occurred. The blood pressure was not influenced except in one patient, who developed a hypertension of between 180/90 and 190/110 during early convalescence; this still persisted after 6 months with clear urine, but is now resolving.

Eyes.—All cases showed the marked injection of the conjunctival vessels and the heavy appearance already described. Subconjunctival haemorrhages were seen in 2 cases, and one of them showed a small superficial retinal haemorrhage. During convalescence one patient complained of "spots in front of his eyes," and examination revealed recent translucent opacities of the vitreous. These were still present after 6 months. One patient complained of blurring of vision, and definite swelling of the disk was found on both sides. He subsequently made a complete recovery. Prior to defervescence in some cases, the pupils became constricted, but not to pin-point proportions, and showed sluggish reaction to light and accommodation. Several of the patients complained of diplopia, and transient squinting was noticed.

Ears.—Transient deafness was often experienced. In one case severe tinnitus and deafness persisted until 2 weeks after defervescence and then gradually cleared up. In another case severe vertigo, with the patient falling to the left, occurred, and still persists after 6 months.

Central Nervous System.—The mental condition has already been described, but again it must be stressed that the improvement with defervescence was not so dramatic as one would expect from the textbook descriptions. Cerebral irritation was indicated by muscular twitching of varying degree in 16 cases (76%). This variation extended from fine fibrillary tremor of the facial muscles to gross twitching of phalanges, wrist, and ankle-joints, and groups of muscles were observed to contract. It was noticed that the more extensive the petechial change the more marked was the state of nervous excitement.

One patient on the sixth day of illness began to twitch in the muscles of the face and hands and to complain of double vision; by the tenth day he had a mask-like facies, and movement of all muscles was slow, death occurring on the fifteenth day. Another patient developed facial tremor during the second week of the fever; and 3 days before defervescence, which occurred on the twenty-first day, he developed the torpid facies and gross twitching of phalanges, wrist, and ankles; this was almost choreic in type, and was not a peripheral tetany. Prowazeki's and Chvostek's tests were negative, and venous congestion had no effect. There was a pseudo-spasticity of the limbs, the deep reflexes were never more than brisk, the plantars were flexor, and there was no Kernig's sign. The nervous manifestations reached their maximum just before defervescence and passed off during early convalescence, when the patient complained of blurring of vision and was found to have bilateral disk swelling. In his case ulnar neuritis occurred early in the febrile stage. He complained of severe pain in the little and ring fingers of the right hand, and this settled down to a dull ache and numb feeling; there was no muscle-wasting, and only the loss of the sense of light touch over the little finger, the ulnar half of the ring finger, and the adjacent part of the palm. This still persists after 6 months.

Fine tremor of the fingers was present in all cases during the febrile stage and passed off during early convalescence, when severe neuralgic pains in the feet and legs were complained of.

C.S.F.—Lumbar puncture was not done as a routine but only in those cases with marked cerebral irritation: in all except one case the findings were normal. In the case already described with torpor, Parkinsonism, and disk swelling, the day before defervescence the fluid was clear, and under pressure of 100 c.mm. There were 261 cells per c.mm.—lymphocytes 74%, polymorphs 25%, endothelial cells 1%—and an abnormal increase in globulin.

Genito-urinary System.—All cases had an initial oliguria followed by incontinence. Four patients at the end of the first week, and the others after the defervescence, complained of pain on micturition, having to strain, and a constant desire to micturate without being able to do so. All cases showed albuminuria, red blood cells, epithelial cells, and cellular casts in the urine, which cleared during convalescence; and during the periods of dysuria Gram-negative motile bacilli were found in non-catheter specimens.

Blood Examination.—There was an initial polycythaemia, which may be attributed to the early low fluid intake, to the fluid lost through forceful respiration, and to that lost secondarily by sweating. The haemoglobin percentage and red blood cells fell by from 20 to 30% and from 1½ to 2 millions respectively after the appearance of the petechial rash. In cases with no petechial rash there was not this proportionate fall. The Hb and red cells were quickly made up during convalescence. The white cells varied considerably; the maximum count was 30,200, two were in the region of 18,000, and of the others the highest was 13,000 and the lowest 4,400. Neutrophils constituted 60 to 83% of the count. The granules in the polymorphs appeared to be coarser and more highly stained than the normal. In the 2 fatal cases the counts were R.B.C. 4,600,000, Hb 72%, W.B.C. 4,400; and R.B.C. 4,860,000, Hb 78%, W.B.C. 6,400—taken on the fifth and seventh days respectively. Small extracellular coccal and cocco-bacillary bodies, occurring in pairs and in clusters, violet in Giemsa-stained specimens, were found in a number of the films. These were presumed to be Rickettsia bodies, and were found in one case 6 months after the onset of the illness.

Blood Sedimentation Rate (200-mm. tube Westergren, one hour).—In one case the B.S.R. readings were: 35 two days before rash, 129 three days before defervescence, 83 twelve days after defervescence, 51 nineteen days after defervescence, and 7 three weeks later. In a case with persistent tachycardia the figures were: 2½ months 91, 3 months 94, 3½ months 20, 4 months 38, and 4½ months 22. In the other cases the B.S.R. was not done frequently, but was in single figures in the second week of convalescence.

Laboratory Findings.—The Weil-Felix reaction was positive in all cases tested after the seventh day of fever; in those done on or before the fifth day a negative return was obtained. It was noticed that in the cases in which no rash appeared the titre was lower (1:80 to 1:800) than in petechial cases (1:200 to 1:6400). Successive titre readings could not be made a basis for estimating the severity of the illness, but a rising titre in one case indicated more severe prostration. The Wassermann reaction was frequently positive, but not invariably so, and this test could not be done often enough to be of value. It always became negative after the defervescence. Blood, stool, and urine culture results were negative, but as the specimens were dispatched a considerable distance they were of no value for culturing.

Post-mortem Findings.—In one case ending fatally on the fifteenth day necropsy revealed the cause of death as haemorrhagic bronchopneumonia. The only other significant findings were a marked diminution in body and mesenteric fat, the occurrence of numerous subpleural haemorrhages, and a vivid scarlet coloration in the left lung. The pons and medulla were sent for section, and the translated German report read:

Pieces of Brain Stem.—There are numerous perivascular nodules of polymorphous glial cells in all parts of the brain stem and in the cerebellar cortex. There are changes in the ganglion cells (chromatolysis) and exuberant growth of red cells. Isolated annular perivascular infiltration of lymphocytes and very small haemorrhages. The meninges are infiltrated with lymphocytes, plasma cells, and macrophages. Signs of brain oedema. *Diagnosis*: Typhus meningo-encephalitis.

The histological report suggests a close association with encephalitis.

Treatment Given

Sulphonamides, sulphapyridine, and the ordinary antipyretics were useless. Neither atebrin nor hexamine had any effect on the course of the disease.

The main part of the treatment consisted in giving fluids with glucose *ad lib.*, and when the patient would not, or could not, take them by mouth they were supplemented by the rectal or intravenous route. By this method up to 5 or 6 litres could be given in 24 hours. When prostration was most severe a glucose-saline with 0.00025 g. of strophanthin intravenously resulted in marked improvement. When there was severe cerebral irritation lumbar puncture resulted in an amelioration of symptoms. In one case 50 c.cm. of serum from a convalescent case was injected intramuscularly. The patient improved considerably, but as he had had an intravenous saline and also a lumbar puncture the same day the improvement could not be attributed to any one factor. Cardiac stimulants were given by mouth during the febrile and early convalescent stages. Luminal and scopolamine–eucodal–ephetonine (omnopon–scopolamine) were effective in controlling the acute delirium and insomnia. Tepid sponging was most effective in relieving mental and physical distress. Oral hygiene and care of the skin were insisted on.

As can be seen, the essential part of the treatment consisted of good nursing.

The complications arising consisted of bed-sores, disk swelling (transient), lung abscess (fatal), partial atelectasis, persistent vertigo, persistent ulnar neuritis, and persistent hypertension.

Diagnosis

The problem of diagnosis is an urgent one during the initial phase and in the milder type of case in which there may be no rash. The differential diagnosis has to be made from, for example, influenza, bronchopneumonia, tonsillitis, acute nephritis, enteric fever, meningitis, acute abdomen, acute encephalitis.

Aids to diagnosis are: (1) Occupation. (2) Presence of lice. (3) Severe frontal headache and fever, with failure to respond to ordinary antipyretics. (4) Typical facies with heavy injected eyes. (5) Acute dyspnoea with disproportionate signs. (6) Absence of neck rigidity. (7) Blood picture: polycythaemia with leucocytosis in which the granules are coarser than normal (in enteric there is usually a relative lymphocytosis). (8) The rash, when and if it does appear, is more profuse than in enteric fever. (9) The Weil-Felix test is the deciding factor, and is seldom positive before the appearance of the rash.

Summary

The principal points of interest in this series of 21 cases are:

The occupational association of the "epidemic."

The occurrence of the rash on the face in 19% of cases.

The blood picture: the main features being: (*a*) the initial polycythaemia,[*] (*b*) the fall in haemoglobin and red cells after the appearance of the petechial rash, (*c*) the occurrence of ? Rickettsia bodies, (*d*) the coarseness of the granules in the polymorphs.

The close similarity between typhus fever and epidemic encephalitis both clinically and pathologically.

The urinary symptoms and findings.

We owe our thanks to Major D. L. Charters, R.A.M.C., ophthalmologist and senior British medical officer, and to Major W. M. Macleod, R.A.M.C., medical specialist, for their helpful advice.

MANAGEMENT OF RHEUMATIC DISEASE IN THE FORCES

BY

OSWALD SAVAGE, M.R.C.P.
Acting Lieut.-Colonel, R.A.M.C.

That the problem of rheumatic disease in the Forces is a considerable one is shown by the fact that out of 2,727 cases seen as out-patients at two military hospitals during the year ended May 1, 1942, 307 were referred because of rheumatism. That is, 1 case out of every 9 was sent up for advice on this account. Just as in peacetime this group of diseases causes great loss of industrial working hours, so, in wartime, rheumatism, though often not severe, interrupts training and disorganizes routine.

It may be of interest to analyse the various groups of cases seen and give a brief account of the treatment adopted and the method of disposal followed. This last is of importance to Service medical officers. Table I summarizes the numbers of each group of rheumatic disease and the percentages admitted to hospital either for further investigation or for treatment.

TABLE I.—*Summary of Cases of Rheumatic Disease in 12 Months at a Military Hospital*

Disease	No.	% of Total Rheumatic Cases	No. Admitted	% of Disease Admitted
Fibrositis	141	52·22	19	13 47
Lumbar	40	14·80	14	35
Trapezial	30	11·10	4	13
Gluteal	26	9 62	—	—
Generalized	18	6 66	—	—
Shoulder girdle	14	5·18	—	—
Intercostal	13	4 81	1	7
Postural backache	40	14 80	12	30
Sciatica	24	8·88	24	100
Osteo-arthritis	24	8 88	7	29
Ankylosing spondylitis ..	14	5·18	12	85
Rheumatoid arthritis ..	5	1·85	3	60
Osteochondritis dissecans ..	5	1·85	1	20
Rheumatic fever	4	1·48	4	100
Infective arthritis	4	1·48	3	75
Gonococcal arthritis	3	1·11	3	100
Sacro-iliac strain	3	1·11	3	100
Spondylolisthesis	1	0·37	1	100
Myositis ossificans	1	0·37	1	100
Gout	1	0 37	1	100
Total	270	100	94	

In 37 cases it was found on examination that there was no evidence of any rheumatic condition. These men were complaining of muscular stiffness after exercise and had labelled themselves "rheumatic" or "arthritic" quite unjustifiably; this diagnosis had been accepted by the unit M.O. Actually the pains were due to the normal physiological response to unaccustomed use of particular muscles. Such men were at an early stage of their training, and it was advised that they should be returned to duty and to normal P.T.

Of the remaining 270 cases 94 were admitted to hospital. The grounds for admission to hospital of men in the Forces suffering from rheumatic disease while they are undergoing training differ widely from the management of civilians in peacetime. Civilians should be treated as out-patients whenever possible so that they can continue to earn a living and avoid the economic anxiety which accompanies hospitalization. With patients in the Services, however, the main purpose must be to render them fit for full duty in as short a period as possible. A soldier with rheumatic disease is of no use in his unit and will usually be stationed too far from a physiotherapy department to be able to attend for daily treatment. In many cases the most rapid way to return the man to full duties is to admit him to hospital, where intensive treatment can be given. Often after a short period in hospital these men are transferred to a convalescent depot where they can continue treatment under P.T. instructors, with the supervision of the Command specialist in physical medicine.

Owing to the type of rheumatic disease encountered in the Services a large proportion can be completely cured, while in the more chronic cases treatment will yield sufficient improvement for the man to be capable of a high degree of efficiency, though in a lower medical category.

Table II summarizes the cases admitted to hospital, their numbers, age, duration in hospital, and disposal.

TABLE II.—*In-patients with Rheumatic Disease during 12 Months*

Disease	No.	Average Age	Average No. of Days in Hospital	Category E
Sciatica	24	29	21	1

Myositis ossificans	1	37	30	1
Gout	1	26	31	*
Total	94			

* Transferred to special E.M.S. unit.

Fibrositis

This formed by far the largest group, being over 52% of the total number of rheumatic cases. The term "fibrositis" as it is usually employed means a non-articular involvement of the soft tissues, most commonly the sheaths of the muscles, the fascial layers, and other fibrous supporting tissues of the locomotor system. No direct evidence of pathology was obtained, but the changes were considered similar to those described by Stockman (1940)—that is, swelling and oedema of the affected areas with proliferation of fibroblasts and formation of new blood vessels. Later the connective-tissue cells proliferate and the area becomes more fibrous and tougher. The aetiology in nearly all the cases was thought to be traumatic, due to small muscle tears taking place during the course of training. In some cases previous industrial fibrositis had been exacerbated by training. Nearly all these men were ex-miners and were recommended for discharge on account of the strong probability of multiple recurrences. Any evidence of local sepsis was rare. In only 7 cases out of the 141, or 5%, was a focus found which might conceivably have played a part in the aetiology. Cases of fibrositis should not as a rule be admitted to hospital unless they require manipulation or intensive treatment. They should be capable of being rendered symptom-free by short periods of physiotherapy, and Army life with its regulated activities and adequate food is often good treatment for them. Lowering the man's medical category was delayed until treatment had been tried. In the majority of cases it was found to be unnecessary.

Lumbar Fibrositis (40 cases).—Fourteen of these had acute lumbago and were admitted to hospital. They were treated by strapping the back muscles longitudinally and by heat. Within a few days spinal movement was encouraged by the masseuse, and they were allowed up. At the end of a week they attended the exercise class and were given work to do in the hospital. In all cases they were returned to their units for full duty (average time 16 days). Of the men treated as out-patients the majority had minor recurrences of fibrositis which had started in civilian life. These men complained of backache intensified by exercise. On examination there was restriction of full spinal movement, with often a localized area of tenderness in the lower erector spinae muscles. Initial treatment in many cases was by local infiltration of 2% procaine. This was followed by daily heat and exercises. As soon as possible these men were put in an exercise class.

Trapezial Fibrositis (30 cases).—These men complained either of post-occipital pain and headache or of stiffness across the shoulders accentuated by wearing equipment and by drill. In 4 cases admitted for treatment the condition was of long standing and there was muscle-wasting. A localized area of tenderness could usually be palpated on the muscle sheath and the pains thus reproduced. This area was infiltrated with 2%

procaine, followed in some cases with proctocaine. Daily exercises were given afterwards.

Gluteal Fibrositis (26 cases).—It is difficult to differentiate these cases from the sciatic group as they both form part of the sciatic syndrome. They were none of them severe, and were all treated as out-patients. The complaint was of pain radiating from the buttock. On examination this could be reproduced by palpation of a localized or diffuse area, most frequently in the origin of the gluteus maximus or medius. Where localized, such an area was infiltrated with an anaesthetic. All cases were treated with heat and exercises, active and passive.

Shoulder-girdle Fibrositis (14 cases).—The symptom here was of pain radiating from the shoulder down the outer side of the arm, often to the fingers, with some pain on full movement of the joint. Deltoid wasting was present in a few. It was considered that the lesion in these cases was in the region of the subacromial bursa: either that the walls of the bursa itself had become adherent or that the bursa was stuck to the overlying deltoid or supraspinatus muscle. Joint change or calcification of the supraspinatus tendon was excluded in each case by radiography. These men were treated by local anaesthetic injected into the region of the bursa. This was followed by active exercises. In the majority one injection was sufficient.

Postural Backache; Sciatica; Osteo-arthritis

Postural Backache (40 cases).—This is a relatively common condition. During the early weeks of training the men report sick with backache. They have usually taken no exercise for some years, have been in light occupations, and are of poor physique. The types of posture have been recently described by Howitt and Wesson (1942): (1) forward slump with down-tilted pelvis, lordosis, kyphosis, and the head carried forwards; (2) sway back with the weight carried on the heels, pelvis horizontal, and a long lumbo-thoracic kyphosis. Spinal movement may be restricted by pain and muscle spasm. These men were all treated by remedial exercises. Those not admitted were recommended to be sent to the Army physical development centre. In 12 cases the overlying muscle spasm was so severe that the men were unable to work and were admitted to hospital. Spinal manipulation under anaesthesia was carried out and they were given remedial exercises. As soon as possible they were transferred to a convalescent depot under the Command specialist in physical medicine. These cases are in the main capable of much improvement, and if seen at an early stage can be cured. Howitt and Wesson (1942) report that 65% can be upgraded and that 50% reach category A1. If these men remain untreated they will become chronic attenders at sick parade, and it is important that this condition should be recognized as a clinical entity occurring not uncommonly in the Army to-day.

Sciatica (24 cases, all admitted to hospital).—Cases of sciatica occurring in units should be admitted to hospital as soon as possible. They need full neurological investigation and often the opinion of an orthopaedic surgeon is called for. Even where the condition runs a short course with steady improvement, full bed rest, trained nursing, and splinting are required. Physiotherapy may be necessary in the later stages. C.S.F. examination was carried out in every case where improvement was not rapid. In 5 cases it was considered that there was an intervertebral disk lesion. They were transferred to an E.M.S. neurological unit for further examination; in 3 a disk lesion was thought unlikely, and in the other 2 manipulation was performed with relief of symptoms, though the possibility of a prolapsed disk remained. In 6 cases the sciatic syndrome was regarded as due to a severe gluteal fibrositis. After a period of rest, infiltration with local anaesthetic was carried out and followed by physiotherapy. In 3 cases sciatica of long standing had proved resistant to physiotherapy elsewhere. Manipulation was followed by restoration of full function. The remaining 10 cases made slow but steady progress. They were treated by rest, splinting, and physiotherapy. When fit they were transferred to a convalescent depot for further exercises.

Osteo-arthritis (24 cases).—The localities affected were: spine 9, hips 8, knees 3, ankle 2, shoulder 1, wrist 1. In all these there was radiological evidence of joint disorganization with osteophyte formation. The average age was 40, which may be considered low, but the younger patients had a history of either previous joint diseases—e.g., Perthes's disease—a single severe injury, or multiple microtraumata due to industrial conditions. Most of the spinal cases were in ex-miners, who were all discharged from the Service.

Other Conditions

Ankylosing Spondylitis (*Marie-Strümpell Disease*): 14 cases. —This is a large proportion for a disease which is counted a rarity. It occurs almost exclusively in young men, and therefore in the age group which was being examined; but, even so, it would appear from this small series that it may be a more common cause of backache than is generally recognized. Twelve of the cases were at an early stage with symptoms of under two years' duration—bilateral sacro-iliac changes in the radiograph, with no calcification of the spinal ligaments. They all had raised sedimentation rates, indicating activity. For example, a private aged 21 had played Rugby football the previous winter. For the past 6 months he had had increasing attacks of backache accentuated by long standing. He had been awakened at night by the pain. In the early stages massage gave relief. Examination produced the following information: height 6 ft. 5 in., back held rigid, lumbar curve flattened, all spinal movement restricted by pain, chest expansion only 1½ in., pain on flexion of right hip; otherwise a healthy man. Radiographs revealed bilateral erosion of the sacro-iliac joints. B.S.R. 30 mm. (Westergren). These men were transferred either to orthopaedic units in the E.M.S. or to spa hospitals. The two cases not admitted were of long standing. Radiographs showed a "bamboo spine," with calcification of the spinal ligaments and ankylosis of the sacro-iliac joints in each case. They were recommended for discharge from the Army.

Rheumatoid Arthritis (5 cases).—This is an uncommon disease in the Army. Three of the cases were in an active phase and were sent on to a spa for further treatment. The other two were inactive and had residual deformity of the hands and wrists; these men were retained in a lower category.

Osteochondritis Dissecans of the Spine (*Scheuermann's Disease*): 5 cases.—These men complained of backache. There was limitation of spinal movement in each case, and radiography showed typical areas of decalcification of the vertebral bodies (Schmorl's nodes). They were referred to an orthopaedic surgeon.

Rheumatic Fever (4 cases).—The average age, 25 years, of this small group is high and in each instance the attack was a primary one. All were seen at an early stage and had migratory pains, swelling and redness of the joints, with fever, tachycardia, and a high sedimentation rate. They were treated with complete bed rest until the B.S.R. returned to normal (average 63 days). When convalescent they were sent to auxiliary hospitals, being returned for check-up before going on to convalescent depots. No demonstrable cardiac complications occurred in any case.

Non-specific Infective Arthritis (4 cases).—In these men joint pain and moderate effusion were associated with a focus of infection. In 3 this was septic tonsils and in the other a dental abscess. The sedimentation rate in each case was normal. The joints subsided rapidly with rest, and the focus was removed surgically later. In one case there was a short relapse after tonsillectomy.

Gonococcal Arthritis (3 cases).—Two of these cases were early, with urethral discharge, and were transferred. The third had a history of recurrent arthritis of the ankles for over 14 years. The first attack was concurrent with gonorrhoea and there had been two reinfections since. A prostatic smear was negative. Treatment was by fever therapy, with three bouts up to 105° F. at 48-hour intervals, produced by intravenous T.A.B. The clinical result was excellent and the man was returned to duty.

Sacro-iliac Strain (3 cases).—All were traumatic in origin. The strain in each case resulted from a sudden effort to recover balance. For example, Pte. B., 5 days previously, had jumped on to a piece of wood which skidded. He made a great effort to regain his balance, and "felt something go" in the right sacro-iliac region. The pain forced him to his knees, and after walking for 10 minutes he had to go to bed. Examination revealed pain on coughing and turning, spinal flexion limited by pain, and pelvis tilted up on the right side with scoliosis above. Lasègue's sign was present on the right side at 60 degrees, with pain in the right sacro-iliac region, and there was tenderness over the sacro-iliac joint. Radiographs disclosed no bony change. Treatment: manipulation under anaesthesia, and exercises started at once; two days later freedom from pain with full movement. All the cases were treated similarly, and each patient was returned to duty within 10 days.

Summary

All cases of rheumatism sent up to a military hospital during a year are analysed.

A brief account of their treatment and disposal is given.

The great majority of soldiers with rheumatic disease can be returned to duty as useful men.

PSYCHOGENIC ILLNESS IN REGIMENTAL PRACTICE

BY

WILFRID L. JONES, M.B., B.S.
Captain, R.A.M.C.

This account is based on 42 cases seen during a period of twelve months. The small number does not admit of any far-reaching conclusions being drawn, but it is hoped that the observations may be of interest in providing another view of psychogenic illness in the Army. The series differs from those described by Sutherland (1941) and Hadfield (1942) in that not all the cases were admitted to hospital or seen by the psychiatrist, and consequently the investigations were not so complete as theirs.

Owing to the small numbers a broad classification has been followed and percentages are not given. The series consisted of:

Psychoneuroses	Anxiety state	19
	Hysteria	21
Psychosis		1
Psychopathic personality		1

Seven cases of anxiety state and 9 of hysteria were considered to be mild reactions. The psychotic patient had endogenous depression, and the patient of psychopathic personality showed temperamental instability of the cycloid type.

Clinical Material

The cases were seen at a medical inspection room serving a large R.A.S.C. unit, one of Royal Engineers, and a detachment of the Pioneer Corps. Thus none were front-line troops. As the units varied in size, composition, and periods of attendance during the twelve months no estimate can be made of the frequency of psychogenic cases. However, it may be mentioned that in a draft of unselected recruits direct from civilian life, consisting of 19 of the 1921 class and 3 of the 1908 class, there were 2 cases of anxiety state, 1 in each age group. In a draft of 50 men of medical category below A2 there were 1 psychosis, 1 anxiety state, and 1 hysteria. Another man, not included in this series, was a stable mental defective. Most of these had had one or more transfers between arms of the Service, and they were not a normal group, being of low medical category. Also the figures are too small to be statistically valid.

The station was a market town in the South of England. No enemy action was experienced in the area during the period under review and the rest of the country was comparatively raid-free. The R.E. unit had been on bomb-disposal work during the winter of 1940-1, but had had no casualties. In no unit was the work exceptionally arduous or highly technical. The billets were satisfactory; leave was taken regularly; and the sick rate, a good index of conditions, was always low, being frequently under 1%.

Age.—The distribution of cases according to age groups is as follows:

Age Group.	20–30	30–40	40–50	50+	Total
Anxiety state	12	5	—	2	19
Hysteria	16	4	1	—	21
Psychosis	—	—	1	—	1
Psychopathic personality	—	1	—	—	1
Total	28	10	2	2	42
Normal	81	18	1	—	100

The "normal" group are the first 100 on the nominal roll of the largest unit attending. The 2 patients over 50 years of age belonged to the Pioneer Corps.

Rank.—Among those with anxiety states were 2 corporals, 1 of whom reverted to private on account of his symptoms, and 2 lance-corporals. In the group of hysterias 1 patient had held a lance stripe for several months before losing it. Only in the one case were the responsibilities of non-commissioned rank considered to play a part in the illness. The other N.C.O. patients were reported to be satisfactory in carrying out their duties.

Previous Service.—The 2 patients over 50 had served in the war of 1914-18. Neither admitted to having then had "shell shock" or D.A.H. or other psychogenic illness. Four had had previous Army service in peacetime. One with an anxiety state was invalided in 1927 with D.A.H. He said that he recovered 6 months afterwards. The precipitating factor in this war was his being torpedoed when crossing from Eire to enlist. Of 3 patients with hysteria 1 was invalided in 1936 with what now appears to have been a hysterical pain in a hernia operation scar. Specific military conditions in the present war were a factor in 2 other cases of anxiety state. One was precipitated by bombing and the other started acutely while digging for an unexploded bomb. One man with hysteria advanced "shell shock" in the evacuation from Dunkirk as the cause of his trouble, and 1 case of anxiety state began after the patient had endured several heavy air raids in London as a first-aid worker. The average length of service was 13 months before the patients reported sick with recognized psychogenic symptoms varying from 2 days to 2 years.

Symptomatology

Only the most frequently recurring symptoms are described here.

Headache.—This was the commonest symptom. It occurred in 16 cases, 15 of which were hysteria, and was the presenting symptom in 13. It was often described as "pains in the head." The headache was aching or throbbing, stabbing or constricting, or was indescribable. The character and site varied with the individual patient, but one feature was constant: it was always related to the wearing of the steel helmet, being either induced or exacerbated by this. Three patients had a possible organic basis for the headache in previous head injury. Another had mixed astigmatism, and 4 others had defective vision corrected by spectacles. In these cases the diagnosis was based on other features in addition.

Defective Vision.—This was a prominent symptom in 6 cases, including the 4 mentioned above. The characteristic feature was that the spectacles provided by the Army, re-checked by the ophthalmologist, did not improve the condition or relieve the headache and that print became blurred after a few minutes' reading. This occurred with any subject-matter, and is akin to the inability of the patients of 1914-18 to read the war news in the newspapers. In this group 4 also had night-blindness, 2 of whom claimed to have strained their eyes with night driving. (In the same period one patient with night-blindness of organic origin was seen.)

Effort Syndrome.—This symptom-complex occurred in 7 cases of anxiety state and 1 of hysteria. In 2 patients it was induced by wearing the respirator at the alert.

Dissociation Phenomena

This term is used to describe the grosser manifestations of hysteria which occurred in 5 cases.

Case 1: Loss of Consciousness with Convulsions.—This occurred in a man who had been out for the evening with some of his comrades. It was the first occasion since his return from leave a few days previously. He was not on good terms with his wife, whom he had married "on the rebound" when he returned from the B.E.F. to find his fiancée engaged to another man. While on leave he had had several quarrels with her because he preferred the company of his male friends to hers. The connexion was pointed out to him, and no further manifestations were seen.

Case 2.—The symptoms were similar to those of Case 1. The patient had reported sick once or twice with headache suspected to be of hysterical nature. He said he had had "shell shock" but had not been under medical care for it owing to the confusion at Dunkirk. He was not aware that arrangements had been made for his further examination in hospital, so presumably this condition occurred in order to impress the medical officer with the gravity of his symptoms. He returned to duty later.

Case 3.—After 3 years' service in peacetime this man was invalided with a painful operation scar in which he was convinced a nerve was caught up. When called up for service with his Army class he was examined by a surgeon, who concluded that the pain was hysterical. He complained of headache that felt as if there was a tight band round the head, defective vision uncorrected by spectacles, and night-blindness caused by the strain of driving at night. He was nervous in air raids. Two relatives had been killed in London, and his child had recently died. He had been deprived of a lance stripe for disciplinary offences. The psychiatrist reported: "This man is of very poor moral type and is a constitutional hysteric. His general intelligence is well below average, his mental age being 11 years. He is a person unfitted for the ordinary duties of a combatant soldier, and under active service conditions in such a unit (R.A.S.C.) could only be a continual source of liability." He was recommended for transfer to the Pioneer Corps. Before the transfer became effective he was admitted to the camp reception station for a minor ailment. There he showed erratic behaviour of a hysterical nature, including pseudo-epileptic attacks. He was admitted to a neurosis centre and then invalided from the Service.

Case 4.—A recruit aged 19 complained of symptoms on exertion typical of the effort syndrome. No psychopathic family history was elicited. Since he had had rheumatic fever 3 years before being called up he had been careful not to exert himself; he had a light job and played no games. There were no clinical signs of a cardiac lesion. Explanation, encouragement, and light exercise produced no improvement, and his admission to an effort syndrome clinic was arranged. The day before he was due to go it was found impossible to wake him at réveillé. He was left alone and came round after 3 or 4 hours. This was thought to be a sign that he did not wish to lose his symptoms, for which he was excused from doing drill, route marches, and guard duty. It transpired, however, that all arrangements had been made for his wedding 3 days hence. He had made no attempt to get leave for it (he knew he was unlikely to get leave, as his admission to hospital had been arranged), and had not tried to postpone the wedding. Thus he endeavoured to shut out the world and his difficulties.

Case 5.—This man of 42 presented the "syndrome of approximate answers." He was seen when charged with absence without leave. His documents showed five similar offences previously. He was very vague in manner, and said he was worried and depressed and wanted to see his wife and children. A medical report revealed a complaint of impotence some months previously. This had not improved, he said. His intelligence seemed below normal, and his commanding officer had gained the impression that he was trying to appear less intelligent than he really was. He had served 7 years in the Regular Army in the early twenties. The psychiatrist reported: "The first impression is one of malingering, and undoubtedly there is considerable conscious exaggeration of the complaint; e.g., he first denied being able to read, but read quite well when encouraged. He exhibits the syndrome of approximate answers: pen–pencil; ink bottle–glass; pin–needle; figures–all one or two numerals out; brown–green; dark blue–pink; red–white. There is mental depression in a person of below average intelligence with a hysterical state. The phenomena are on the borderline between conscious and unconscious." He was admitted to a neurosis centre.

Case-taking

Any soldier appearing on sick parade with a complaint suggestive of psychogenic illness was told to remain until the others had been dealt with. He was then seen alone, and there was ample time to hear his story. The first interview usually lasted half an hour. A full history of the complaint was taken and questions were directed to a brief personal history from childhood, school work, civilian occupation, hobbies, attitude towards service, and family history.

Intelligence was not formally tested, but a rough assessment was made from memory and comprehension of details in the history, school-leaving age, and class attained, and the type and frequency of change of employment. It was found useful to ask the weekly wage, and then, "How much is that per year?" Officers and N.C.O.s could provide evidence of the patient's general attitude and response to training. Fourteen men with hysteria, 1 with an anxiety state, were considered to be mentally backward. This was confirmed by the psychiatrist in 8 cases.

The patient was examined as fully as facilities allowed, and was referred to the appropriate specialist for an opinion on any physical disability claimed. It was found in 15 cases that a sympathetic hearing and a full examination, and reassurance and perhaps a change of conditions and mild sedation, sufficed to keep the patient at duty. The psychotherapy was not carried out in more than three or four interviews, and was on the lines described by Ross (1937). If this failed or was obviously likely to be insufficient the patient was sent to the area psychiatrist for advice as to disposal.

Disposal

Twenty-two patients remained at duty. Of these, 2 with chronic anxiety states were placed in Category C (home service only) and were posted to other units, as were 5 others; the 15 remaining under observation—8 who had an anxiety state and 7 who had hysteria—have not made further complaint. Five soldiers were invalided from the Service while with their units. They were a man of 52 with an acute anxiety state, 3 chronic hysterics, and the patient of unstable temperament. One man with a chronic anxiety state and 2 men with hysteria based on mental defect were transferred to the Pioneer Corps. Of 9 patients admitted to E.M.S. neurosis centres, 1 with effort syndrome returned to his unit improved, and it is known that 1 patient with hysteria and 2 with anxiety state were invalided. One of 2 patients originally admitted to non-psychiatric hospitals returned to duty. The fate of the other 6 patients is not known, as no reply was obtained to requests for information. The results are tabled below.

Condition	Disposal	Cases
Anxiety state ..	At duty	8
	Transferred to P.C.	1
	Invalided	3
	Unknown	7
Hysteria	At duty	9
	Transferred to P.C.	2
	Invalided	3
	Unknown	7
Psychosis	To military mental hospital	1
Psychopathic personality ..	Invalided	1

Discussion

The "anxiety" of the anxiety state is derived from the German *Angst*, which is usually rendered as "morbid fear." In the cases of anxiety state this was the chief feature, and the symptoms could be regarded as the physical concomitants of fear, in whole or in part, misinterpreted or unrecognized by the patient. In hysteria the clinical features are: (1) a physical manifestation without structural lesion; (2) a calm mental attitude—the *belle indifférence* of Janet; (3) episodic mental states indicative of dissociation (Henderson and Gillespie, 1936). In the cases seen the physical manifestation was the presenting complaint, and the degree of dissociation varied from simple non-recognition of the cause to complete dissociation as shown by the hysterical fit and loss of consciousness. It could not be said, however, that *belle indifférence* was a feature. The patients showed true anxiety, an emotion compounded of desire and fear, which caused them to report sick. There was always the desire, more or less unconscious, to escape from military service or an unpleasant duty, such as guard duty. The steel helmet, worn on guard or in active operations, caused abnormally severe headache; spectacles failed to correct defective vision; night-blindness was discovered; epigastric pain and vomiting persisted in spite of negative physical findings and repeated reassurance. These disabilities offered them an honourable escape from military service, but, unlike the patients of 1914-18 with such obvious physical signs as paralysis or contracture, they could not be calm and confident. There was fear, also unconscious, that they would not attain their desire.

Hysteria was the reaction of the man of subnormal intelligence when conditions became too unpleasant or difficult to cope with. In several the reaction was only episodic, and if they could be helped through the crisis by a change of conditions, or advice on their worries, or encouragement, they would settle down again. It is debatable whether this is a sound policy, as there is no sure means of gauging if the soldier will remain stable in the stress of battle. The medical officer must weigh the patient's present against his potential value as a soldier, and must also consider the effect on morale. Few can watch an unemotional hysteric return to civilian life without questioning the genuineness of his disability, whereas the man with an acute anxiety state is obviously ill. Transfer to the Pioneer Corps and recategorization to C are a partial solution, but there are still some men who, though physically sound, are psychologically unfit for military service.

Capt. G. R. Peberdy, R.A.M.C., deserves my thanks for much help and encouragement in dealing with these patients and for permission to quote from his reports in Cases 3 and 5.

Medical Memoranda

Exfoliative Dermatitis in the Newborn

As exfoliative dermatitis in newborn children (Ritter's disease) is generally mentioned in textbooks as a fatal disease, the following cases, which responded to treatment with proseptasine in large doses and 1% aqueous gentian violet, are worth recording.

CASE REPORTS

Case 1.—I was called in by the district nurse to see a male baby 10 days old. She told me that at 7 days it had developed jaundice and that on the morning of the tenth day "it was a curious colour and its skin was coming off." On examination I found a well-developed baby, but with a curious bright pink colour reminiscent of CO_2 poisoning. The epidermis was so loosely adherent to the underlying tissue that in handling it this was removed, leaving exposed a red raw corium, most marked on the back and buttocks. There were no bullae—a feature in pemphigus neonatorum. Knowing that this was generally a form of impetigo and was apt to develop into a staphylococcal septicaemia, and being aware that babies stand the sulphonamides well, I gave 1.5 g. of proseptasine in milk at once and ordered 0.5 g. to be given 4-hourly, and had the body dabbed with 1% aqueous solution of gentian violet wherever the skin was broken. The temperature was normal, as is usual, and fortunately the baby was breast-fed and sucked well. The next day the condition was subsiding, though fresh places were breaking out and the lips and the mucous membrane of the mouth were infected. The child had not been sick, took its food well, and was comfortable—in contrast with the previous evening, when it had screamed most of the time. I continued the proseptasine for 5 days, reducing the dose from 0.5 g. every 4 hours to three times a day after the second day, and allowed a bath with a weak solution of potassium permanganate on the fourth day of infection. After 3 weeks the child was putting on weight, the skin was returning to normal, and I could foresee no further trouble.

Case 2.—This child was attended by the same district nurse and was 13 days old. I saw it the day after I had seen Case I. The condition was not so pronounced, the skin coming off mostly on the flexors and face. The eyelids were affected and the eyes were gummed up. I gave similar treatment, and also anointed round the eyes with yellow oxide of mercury. This child had also nearly returned to normal 3 weeks later.

The second patient was perhaps infected by the nurse before the extreme infectiousness of the condition was realized, and the infection lessened in transit. Both cases recovered after large doses of proseptasine and a 1% solution of gentian violet.

Reviews

THE MEDICAL ANNUAL

The Medical Annual, 1942 A Year Book of Treatment and Practitioner's Index. Sixtieth Year. Editors: H Letheby Tidy. M D., F.R.C.P., and A. Rendle Short, M.D, F R C S (Pp 396; illustrated. 25s.) Bristol: John Wright and Sons; London: Simpkin Marshall, Ltd

Once more in the familiar green cover the *Medical Annual* makes its yearly appearance, suffering, as so many of us have done during this war, from a slight loss of weight due to rationing. Nevertheless all the familiar features are preserved. The customary "Introduction by the Editors" puts into focus the medical events of the past year, and at the same time gives the reader valuable guidance to the detailed contents, which are arranged, as usual, alphabetically. Subjects which have come to the fore during the war, such as mass radiography and dyspepsia in the Forces, the application of psychology to the selection of personnel, the treatment of burns, and blood transfusion, are all naturally given prominent place. An article on shelter health by Lord Horder reminds us of the turmoil of about two years ago, and the Editors take the opportunity to commend the part played by the Horder Committee in the solution of shelter difficulties. We note one small point, and that is the editorial use of the word "oestrin" as if it were an accepted physiological term, whereas it is in fact a proprietary term.

It is, as the publishers remark, now no secret that their works at Bristol, together with valuable plant and a large quantity of stock, were destroyed by enemy action, and the present volume has been produced at Weston-super-Mare. The medical profession will wish them well in the valuable part they continue to play in medical publishing.

NON-PULMONARY TUBERCULOSIS

Non-pulmonary Tuberculosis. By Michael C. Wilkinson, M B, B.S. (Pp. 174; 12 figures. 12s 6d.) London. Hamish Hamilton Medical Books. 1942.

This book embodies the experience gained by the author in the observation and treatment of cases of non-pulmonary tuberculosis in a sanatorium over a period of seven years, and a follow-up survey of 593 cases treated in this institution. The whole field of non-pulmonary tuberculosis is covered, including glandular, abdominal, genito-urinary, and parietal thoracic tuberculosis, as well as tuberculosis of bone and joints. Treatment of the last-mentioned conditions is therefore not dealt with in anything like so much detail as it is, for example, in Mr. Girdlestone's book on tuberculosis of bone and joints, published in 1938, the author concerning himself with general principles of treatment and the indication for and timing of operative intervention rather than with details of operative technique, which are, however, not entirely omitted. Stress is rightly laid on the paramount importance of prolonged and adequate constitutional treatment before surgical intervention is undertaken. The latter is necessary in most cases, but should be considered only as an adjuvant measure to be used at the right time in each individual case.

The author regards the lymphatic glands as a defence mechanism, and notes that children who develop tuberculous adenitis do not, as a rule, subsequently get haematogenous infections, though he admits that the defence may break down in debilitated patients or those exposed to massive infection. This is somewhat at variance with Mr. Girdlestone's contention that heavily infected tuberculous glands cease to be protective and become themselves a source of bacillaemic showers and haematogenous infections. Tables of end-results are given for each class of case and these are interesting and valuable, but their value would be greater if brief details were given of the clinical, *x*-ray, or laboratory findings on which the diagnosis was made rather than a general statement that it was made on good evidence, especially in cases where good movement of a tuberculous joint is claimed. Diagnosis by excision of a regional gland is mentioned in the case of the knee, but not of the hip-joint, though excision of iliac glands has already given a number of positive results in the latter cases.

The book, though it contains nothing actually new, is of undoubted value as a first-hand record of practical experience and shrewd observation in this field, and, as such, can be read with advantage by all those concerned with the treatment of tuberculosis from whatever point of view they may approach the problem.

CONTEMPORARY PHYSIOLOGY

Annual Review of Physiology. James Murray Luck, Editor; Victor E. Hall, Associate Editor. Vol 4. (Published by the American Physiological Society and Annual Reviews, Inc.) (Pp. 709. $5.00.) Stanford University, California: Annual Reviews Inc. 1942.

This volume contains references to nearly four thousand original papers, and to about the same number of authors' names: the task of selecting these from the enormous bulk of contemporary literature must have been enormous, though, of course, there is great variability in the available numbers of papers relating to the different reviews. The largest number no doubt are those that refer to the physiology of reproduction, and this review lists 486 references; in a relatively restricted field such as in the review on the physiological effects of neutron rays only 31 references are given. It is probable that reviews covering more restricted fields, such as the latter one, are able to quote a larger fraction of the published work than are the ones dealing with richer bibliographical resources. Further, the treatment in such reviews has the opportunity to cover its ground in a more leisurely and thorough manner, and so to be more generally instructive than that of the overcrowded branches of the subject.

It would be difficult to pick out any of the reviews for detailed comment, since each is itself a condensation of so much. The following is a list of the reviews. Permeability, by L. R. Blinks; the physiological effects of neutron rays, by P. C. Aebersold and J. H. Lawrence; physiological aspects of genetics, by H. H. Strandskov; developmental physiology, by H. L. Hamilton and B. H. Willier; water metabolism, by J. P. Peters; growth, by G. S. Avery; energy metabolism, by W. H. Chambers, E. Shorr, and S. B. Barker; the physiology of the skin, by P. C. Baird, jun., W. F. Lever, and T. D. Spies; the peripheral circulation, by A. B. Hertzman; the heart, by M. B. Visscher; the blood, by H. P. Smith; the digestive system, by E. J. Van Liere; the kidney, by J. A. Shannon; electrophysiology, by R. W. Gerard; the spinal cord and reflex action, by T. C. Ruch; the central nervous system, by M. Hines; the autonomic nervous system, by K. Hare and J. C. Hinsey; sense organs, by H. K. Hartline; metabolic functions of the endocrine glands, by C. N. H. Long; the physiology of reproduction, by F. L. Hisaw and E. B. Astwood; physiological psychology, by C. P. Richter; applied physiology, by A. R. Behnke and C. S. Stephenson; and the pharmacology of drug addiction, by M. I. Smith.

TREATMENT OF VENEREAL DISEASE

The Modern Treatment of Venereal Diseases. By E. T. Burke, D.S.O., M.B., Ch.B. (Pp. 105. 12s 6d.) London: John Bale Medical Publications, Ltd. 1942.

Burke's *Modern Treatment of Venereal Diseases* contains essentially the same subject-matter as the treatment section of his larger book, *Venereal Diseases*, published in 1940. Most syphilologists will remember that Burke was a strong advocate of the alternating–continuous method of treating syphilis and of the use of oil-soluble bismuth to the almost complete exclusion of all other preparations of this metal, and that his plan of treatment is worked out according to his "efficiency index." A discussion of this last is not possible within the scope of a short review, but while the theory is ingenious in conception it has not been adopted by any considerable number of syphilologists. Mercury is recommended only in the form of collosol mercury sulphide, and "mercury pills, mixtures, and inunctions constitute, at the present day, a reprehensible trifling with the future well-being of the patient"; on the other hand, great faith is placed in iodine, especially in late syphilis. The account given of the reactions produced by antisyphilitic agents is good, but more might have been said with advantage about post-arsphenamine jaundice and its treatment.

Nearly three-quarters of this little book are devoted to syphilis, only some 28 pages being allotted to gonorrhoea, chancroid, and other forms of venereal disease. The optimum dosage of sulphonamides in gonorrhoea is not yet settled, but few will agree with a comparatively low one extending over 14 days; a fuller account of the toxic effects of these drugs and their treatment would have added much to the value of this book, as would a section on non-gonococcal urethritis, which appears to be very much on the increase. Many people regarded Burke as a crank, but he was a crank of very wide experience, and a study of this his last publication is recommended to all venereologists, who will be able to sift the grain from the chaff; repeated references in this book to the large volume are not very helpful, since the possessor of the latter will hardly need to read the former. The price appears to be disproportionate to the size, even in these wartime days.

Notes on Books

The fourth edition of Prof. F. J. BROWNE's now famous textbook, *Antenatal and Postnatal Care,* is no "austerity" volume. It has been completely revised and drastic pruning has improved the final product. Pages have been saved by transferring the bibliography to the end of each chapter, and although much new material has been added the edition is a little smaller than its predecessor. As the field it covers becomes ever wider this book will soon be outgrowing its title, indeed there is some evidence to suggest that it has done so already; but whatever its name should be the seven-year-old will be welcomed and generally acclaimed as the best edition yet printed. It is published by J. and A. Churchill at 24s.

The first edition of HOLMES and RUGGLES's *Roentgen Interpretation* was published in 1919, and it is an index of the popularity of this excellent little handbook that it has now reached its sixth edition (Henry Kimpton; 24s.). The standard has been well maintained in this, and there are few criticisms to offer. Some of the illustrations, in the section on the urinary tract particularly, might with advantage be replaced by more modern ones. Many radiologists will regret to see that the authors recommend the practice of setting fractures and removing foreign bodies under the fluorescent screen. The book makes no pretence of being a complete account of diagnostic radiology, but aims rather to give a condensed survey for students seeking an outline of the subject. In this the authors succeed very well, and the volume is to be recommended for this purpose.

Preparations and Appliances

GONADOTROPHIC HORMONE FROM PREGNANT MARES' SERUM

Messrs. Boots manufacture a gonadotrophic hormone from the serum of pregnant mares called "antostab," which is supplied as a dry powder together with a solvent of saline and 0.3% tricresol. It is standardized in international units, 1 I.U. being the activity of 0.25 mg. of the hormone; usually a course of six injections of 200 I.U. given intramuscularly twice a week is suitable for most cases, though the dose must be adjusted individually. It is recommended for trial in cases of amenorrhoea, sterility of ovarian origin, and selected types of irregular bleeding, but should never be used until a thorough examination has excluded general and pelvic disease. While there is as yet insufficient clinical evidence to evaluate the hormonal treatment of disturbances of menstruation, there is no doubt that the gonadotrophic hormone from the serum of pregnant mares should theoretically be of considerable value, and on the basis of animal experiments it is more potent than the hormone of pregnancy urine.

VITAMIN K ANALOGUES

Menaphthone-Boots and acetomenaphthone-Boots are synthetic vitamin K analogues which have the same physiological properties and are more potent than natural vitamin K. Menaphthone is the approved name for 2-methyl-1 : 4-naphthaquinone and acetomenaphthone is 1 : 4-diacetoxy-2-methylnaphthalene. Menaphthone and acetomenaphthone are indicated in the treatment of neonatal haemorrhage and in conditions where digestion of fats is disturbed or inhibited or absorption deranged—e.g., obstructive jaundice, biliary fistula, idiopathic steatorrhoea, and coeliac disease. Menaphthone is supplied in ampoules as an oily solution for intramuscular injection, and acetomenaphthone in tablets for oral administration. Literature and samples will be sent on request to the Medical Department, Boots Pure Drug Co., Ltd., Station Street, Nottingham.

THE ANATOMY OF CUTANEOUS SENSIBILITY

The increase of peripheral nerve injuries related to war conditions, and, more particularly, their segregation in special centres for treatment, have again focused attention on the anatomy of cutaneous sensibility. Von Frey is often credited with having established the relation between specific nerve-endings and specific modalities of sensation. Dallenbach[1] has pointed out, however, that in reality von Frey was more cautious in his statements. Recently, Gilmer and Haythorn[2] have attempted to identify skin-pressure vibration spots with nerve-endings beneath them. Using a variety of staining methods and thin serial sections of biopsy material they were unable to find endings of one particular type beneath the spots. They stated, however, that all the staining methods employed were unsatisfactory in that no single stain demonstrated all the nerve elements they wished to study, and it was thus necessary to treat a number of the sections by different methods. They tentatively concluded that richly innervated arteriovenous anastomoses might be in some way related to the sensory interpretations, for in several biopsy specimens such bodies were present just beneath the sensitive spots. Woollard *et al.*,[3] on the other hand, brought forward very good evidence that specific endings at different depths beneath the skin subserve specific modalities of sensation, and they also showed that cutaneous pain is subserved by a morphologically specific type of nerve termination. Weddell,[4] proceeding on the lines indicated by Woollard, has insisted on the need for examining large whole preparations of skin, including the underlying tissues, to get a true picture of the relation of a sensory "spot" to its subjacent nerves and endings. For this purpose he uses vital staining with methylene blue to demonstrate both the nerve fibres and their endings. By such methods it has been shown that sensory "spots" in the skin overlie more than one individual nerve-ending (or group of endings) of the same type, and that the nerve fibres subserving the endings (or groups of endings) are not a series of collaterals derived from one nerve fibre, but (as far as they can be traced) are separate fibres which approach the "spot" from different directions. For example, it was found in one case that situated beneath a cold "spot" were two groups of Krause's end-bulbs lying at a depth of 1 mm. beneath the skin surface and separated from each other by 3 mm. It has also been demonstrated (Weddell[5]) that in a human finger pad, an area of acute tactile sensibility, large Meissner's corpuscles are situated in groups of two or three, each ending connected with a single unbranched nerve fibre. In addition, it has been shown that, while in the finger pad certain nerve fibres are surmounted by single Meissner's corpuscles, in the forearm a single nerve fibre may give rise to a number of separate Krause's end-bulbs; and, furthermore, cutaneous pain is shown to be subserved by terminal networks which spread over still larger areas. For example, a single nerve fibre in the dorsum of the hand has been found to give rise to a terminal network of fine-beaded fibres covering an approximately circular area of maximum diameter 0.75 cm. In confirmation of such histological findings, Tower[6] has been able to show by electrophysiological methods that the terminal ramifications of a single afferent fibre from the rabbit's cornea comprise a unit area of from 50 to 200 sq. mm., the area having sharply defined limits. She has suggested the term "sensory unit" for such terminations, on the analogy of the "motor unit."

Thus, it becomes clear that a sensory "spot" is not synonymous with a single nerve-ending at the end of a single nerve fibre. "Spots" overlie groups of specific endings which lie at some depth from the surface and are borne upon separate nerve fibres. It also appears that a "spot" need not immediately overlie one particular ending or group of endings, but is so situated that the application of the stimulus affects the maximum number of subjacent specific terminals. The failure of Gilmer and Haythorn to find specific nerve-endings beneath skin-pressure vibration spots is thus hardly surprising, but, as explained above, their failure is not an argument in favour of the non-specificity of cutaneous nerve terminals.

It has been suspected for some time that the innervation of sensory "spots" is not simple; in fact Head[7] found it necessary to postulate two collateral systems of nerve fibres (protopathic and epicritic) to account for his observations on the return of cutaneous sensibility after division of a cutaneous nerve. Boring,[8] on the other hand, was led to infer a multiple innervation of sensory "spots" by fibres of one type to explain his own observations after division of a cutaneous nerve. In a recent critical review on the anatomy and physiology of cutaneous sensibility Walshe[9] has shown that the histological findings of Woollard and Weddell form a concordant anatomical basis for the careful clinical observations of Trotter and Davies,[10][11] who repeated and elaborated the work of Head from a quantitative rather than a qualitative point of view. As Walshe points out, the work of Trotter and Davies has not received the attention and credit which are due to it from neurologists. To quote a passage from his review: "In view of the richly suggestive character of Trotter's writings upon cutaneous sensibility it is striking how little influence they have exerted, and the cynic might submit that this is because he coined no new words to adorn his exposition. The sway exercised upon the imagination of neurologists and physiologists by the words 'epicritic' and 'protopathic' may have had not a little to do with the continued currency of the hypothesis which was their setting."

THE DEMAND ON THE BLOOD DONOR

The general acceptance of blood transfusion as a practicable form of treatment can be dated at 1922, when there were 13 calls on the British Red Cross Society Blood Transfusion Service. In 1930 the number had risen to 1,627. The service was still confined to London, and, though the curve continued to rise, the rate of acceleration slowed down for the next five years.[12] At that time a transfusion was synonymous with the administration of a pint of fresh blood, but the work of Marriott and Kekwick[13] on massive drip transfusion in 1935 led to a considerable increase in the size of individual transfusions and in the indications for the operation. Further increases have come with developments in the use of stored blood, serum, plasma, and concentrated red cells, and the provision of blood banks and depots for the emergencies of war. It needs to be emphasized in looking to the future that while the war has accelerated the provision of facilities the increase in blood transfusions is not due to war needs but to technical advances in blood storage, and that an even sharper rise occurred in America at a time when there was no thought of preparation for hostilities.[14] A modern general hospital in this country can already be expected to be using at least 1,000 pints of blood and plasma a year on purely civilian needs—in particular, medical ailments, diseases of women, and accidents of childbirth—and our planners who think in terms of a 1,000-bed hospital for a town with a population of 100,000 must remember to include in their health centre a blood transfusion service capable of collecting not less than 3,000 pints of blood per annum.

[13] *Lancet*, 1935, **1**, 977.

As early as 1931[15] it had been learnt that individuals might donate a very large amount of blood over a short period of time with surprisingly little effect on the blood count, though it was felt that the ideal amount was 400 c.cm. for males and 300 c.cm. for females, and the interval not less than three months. By the summer of 1934 the silver bar which is awarded for giving 50 transfusions had been conferred twice by the British Red Cross Society[16]; and in 1936 a Paris letter[17] mentioned a donor who had given a total of 257 litres of blood, including 98 transfusions of approximately 300 c.cm. each in the year 1935. This implies the regeneration of about 2% of haemoglobin a day and the assimilation of 300 mg. of iron a week, which would not be within the compass of the marrow unless extra iron was supplied. Exceptional feats must not blind us to the fact that repeated blood-letting is a stringent test of the efficiency of the haemopoietic system and the adequacy, or rather supereminence, of the diet. A strong note of caution was sounded by Snapper and co-workers in 1939.[18] In a study of 101 professional donors in China they found 76 with subnormal blood counts. The frequency and extent of anaemia increased with the total amount of blood withdrawn or the duration of service. Poor diet was considered to be an important factor in the sluggish haemopoietic activity. Treatment with large doses of iron resulted in prompt improvement in the anaemia in most of the cases, while cessation of blood donation alone was uncertain and less effective.

These observations indicate the need for careful supervision of British donors after three years of wartime restrictions on diet, the enlistment by the fighting Services of many of the robust young adult males, and the greater use of females and less fit age groups. Surveys, published[19] and unpublished, show that at the present time many women in the reproductive age group are anaemic, and suggest, though with less assurance, that the incidence of anaemia is increasing. Transfusion officers are beginning to realize the need for checking the haemoglobin level before bleeding and for prescribing iron for the prevention and treatment of anaemia in blood donors. A good deal of work remains to be done in determining the optimum dosage of iron and the necessary duration of treatment. Santy[20] worked with a small group of professional male donors who gave blood at an average rate of 132 c.cm. a week over a period of 12 weeks. The number of donations per donor averaged 4. Using exsiccated ferrous sulphate in a dosage equivalent to 250 mg. Fe$^{\cdot\cdot}$ a day, he found that the haemoglobin was regenerated eight times as quickly when the donors were receiving iron, and that the recovery period was shortened to ten days. He suggested that professional male donors receiving iron could be expected to give 500 c.cm. of blood at fortnightly intervals without lowering the haemoglobin level. His results cannot be transferred directly to the non-professional female donor, but they confirm the efficacy of iron. Fowler and Barer[21] found that a donation of 300 c.cm. of blood reduced the haemoglobin on the average by 10%, and 550 c.cm. reduced it by 18%. Without iron, regeneration took 50 days, but with iron and ammonium citrate equivalent to 200 mg. Fe$^{\cdot\cdot\cdot}$ a day it was reduced to 35 days. The administration of iron had progressively less effect after successive bleedings. The scale preparation of iron seems therefore to have been a good deal less effective than the ferrous salt.

From this and other evidence we may conclude that, provided the diet is supplemented with adequate amounts of medicinal iron, men and women can give blood with safety, and without deterioration of haemoglobin levels, far more often than is ever likely to be asked of them as voluntary transfusion donors. Nevertheless the range of human variation in erythropoiesis is likely to be wide, and supervision should be careful. It seems unwise to bleed a donor whose haemoglobin is below 11.7 g. per 100 c.cm., or 85% on the Haldane scale. Such volunteers should be advised to take iron and be seen again after an interval. For administrative reasons it may be simpler to prescribe iron for all donors after bleeding. Treatment will probably be most successful and acceptable if it is relatively intensive and of short duration; but this is a matter for further study.

THE PERSONAL FACTOR IN ACCIDENTS

The Medical Research Council has recently reconstituted the Industrial Health Research Board on a wider basis, which includes, to a greater extent than before, the prevention and relief of sickness resulting from the particular health hazards to which industrial workers are exposed. Among these hazards accidents loom large, and there has been a considerable increase of them during the war, chiefly owing to the employment of greater numbers of people, many of them inexperienced. In Emergency Report No. 3 the personal factor in accident causation is discussed.[22] The report is based largely on studies made by investigators on the staff of the Health Board, and it is suggested that these studies ought to prove an effective ancillary to the preventive and protective regulations of the Ministry of Labour and to the propaganda of the Royal Society for the Prevention of Accidents. The first part of the report briefly summarizes the influence of environmental factors, such as hours of work, heating and ventilation, lighting, age and experience, on accident liability, while the second and main part is almost entirely concerned with the subject of accident-proneness. It is pointed out that the gravity of an accident depends largely on chance circumstances, and as it has been found that accident-proneness is a relatively stable factor, it follows that persons who are found to be liable to incur minor accidents more frequently than the average are likewise more liable to incur major accidents. In order to identify these accident-prone persons, various psychological tests have been applied to large groups of comparable subjects, working under similar conditions, and it has been found that tests involving rapid and accurate hand and eye co-ordination serve to differentiate them in some degree. Thus the worst 25% of the groups tested had, on an average, twice as great an accident rate as that of the best 25%. In assigning fresh workers to relatively dangerous occupations, such as those requiring the use of presses, it would therefore be distinctly advantageous to choose them from those who did best at the tests rather than from the general average. The results so far obtained show that the tests are valid for prediction among skilled workers only.

[22] *The Personal Factor in Accidents.* Industrial Health Research Board. Emergency Report, No. 3. H.M. Stationery Office. (4d.)

In most factories psychological tests are seldom used as a routine method, so the accident-prone have to be identified on the basis of their previous accident records. This method does not detect the accident-prone so well as the psychological tests, and if the workers happen to have been assigned to rather dangerous occupations their susceptibility may prove disastrous to them before its existence has been realized. It is therefore desirable that workers who are to be put on somewhat dangerous machines should be chosen only from those who have previously been tested psychologically, or who have shown, by their record in other and comparatively safe occupations, that they are not to be classed with the accident-prone. Best of all would it be to employ workers who have demonstrated their quality by both the methods mentioned. In some occupations, such as the driving of motor vehicles, it may be difficult or impossible to apply the double test from the start, but if a group of would-be drivers are first selected by means of the psychological tests, and then are selected afterwards on the basis of their accident records, there can be no doubt that the successful survivors of the tests will have a lower accident rate than unselected groups. It is not to be imagined that accident-prone persons are to be deprived of all employment, for there are many occupations in which accidents are infrequent and in which those that do occur are trivial. It is only from the more dangerous occupations that they ought to be warned off.

If proper use is to be made of our knowledge of accident causation, it is most important that adequate accident records be kept. In many factories the records give merely the total number of accidents attended to, or only those of sufficient gravity to earn compensation. Each worker, whether he has sustained an accident or not, should therefore have a card made out for him when he is first employed, on which should be recorded all accidents, trivial and serious. Records of minor ailments treated at the ambulance room may with advantage be kept on the back of the same card.

THE EPIGLOTTIS IN ANAESTHETIC DEATHS

Healthy scepticism regarding alleged new observations in medicine is always advisable, but if carried too far it may lead to the neglect of important new facts. In an article in the current issue of the *Journal of Laryngology* (May, 1942) Mr. G. H. Caiger suggests that this has happened in regard to impaction of the epiglottis during anaesthesia. It is interesting to review the course of events. Careful comparison of the independent clinical observations published by four separate observers shows agreement on all chief points; when pieced together they present an interesting and instructive sequence. About 1908 Col. F. J. Palmer of the I.M.S. observed that the epiglottis was capable of causing respiratory obstruction under anaesthesia. Later experience confirmed this observation. More than one patient apparently moribund was resuscitated by a finger in the pharynx restoring the epiglottis to its normal position. As years went by and case after case repeated similar experience, Col. Palmer became convinced of the value of his discovery. His colleagues, however, remained sceptical. The anaesthetist concerned in one such case of dramatic recovery declined to believe that the manipulation of the epiglottis into position, so freeing the airway, had been the cause of it, but suggested that there had been a rallying of the heart, or some other such cause, to explain the revival. Met with such scepticism, Palmer did not publish his observations for some fifteen years. Then in this *Journal* on Aug. 25, 1923, H. Mortimer Wharry described in a letter a case in which a membranous epiglottis had caused serious respiratory trouble during a tonsil operation; displaced backwards over the larynx, and adherent to the pharyngeal wall by sticky mucus, it was acting as a valve, permitting air to escape from the windpipe but preventing its entry. When the epiglottis was replaced by the finger, the airway being thus restored, breathing began again and the operation could be completed. Arguing from this experience Wharry recommended that in every case in which unexplained dyspnoea occurred under anaesthesia the larynx should be examined digitally. Apparently encouraged by Wharry's letter, Palmer on Dec. 1, 1923, recorded his observations before a Division meeting of the B.M.A. in Assam, and on Feb. 23, 1924, described them in a letter in these columns. G. H. Caiger, then house-surgeon at Bart's, read this letter with special interest, having lately had an apparently unexplained death of a patient under anaesthesia during operation for hernia. Shortly after, at a tonsil operation where he was present, the respiration failed and he was allowed to make a digital examination of the larynx, found the epiglottis impacted in the larynx, and was able to release it "with an audible click." Respiration became normal and the operation was completed. On May 21, 1927, H. M. Wharry, in a three-page article in the *Journal*, said that since 1923 he had seen "three cases of complete obstruction . . . and many cases of partial obstruction due to this cause"—impaction of the epiglottis. He refers to its "pernicious valve-like action," and points out that in these cases artificial respiration is of no avail until the epiglottis has been raised by the finger and pressed against the back of the tongue, where it should be held till danger is past. Following on this article by Wharry, G. H. Caiger (*Journal*, Aug. 6, 1927) recorded that during 3 years he had seen no fewer than 8 cases of epiglottic impaction. The suggestion was further made that displacement of the epiglottis might be a factor in causing asphyxia neonatorum. (Col. Palmer's paper, read in December, 1923, was first published in the *Indian Medical Gazette* in April, 1928.) Further independent confirmation was forthcoming in 1931-2, in a short article published in *Schmerz-Narkose-Anaesthesie* by Robert Saniter. He notes the absence of any adequate reference to the matter in any of the current textbooks. He finds two fingers of the left hand, introduced well to the back of the throat, gripping the epiglottis, and lifting it up, with the base of the tongue, to be "incomparably more effective" than the usual methods of drawing the tongue forward or pushing the lower jaw forward. It often obviates the need for artificial respiration. He considers its immediate adoption as the method of choice, advisable in all cases of respiratory obstruction. In this present article G. H. Caiger deals in detail with the anatomy and physiology of the epiglottis and the mechanism of impaction. He concludes as follows: (1) The danger of epiglottic impaction during anaesthesia is not sufficiently recognized. (2) A considerable proportion of unexplained deaths under anaesthesia may be due to this unsuspected cause. (3) There are good and sufficient reasons for the lack of post-mortem evidence. (4) Digital examination of the larynx and release of the epiglottis has repeatedly saved patients apparently moribund; this should always be borne in mind in respiratory failure. The article deserves to be widely read.

SHORTAGE OF PRACTISING MIDWIVES

The number of midwives on the roll in England and Wales is just over 65,000, and is increasing, but the number actually in practice as such is only some 15,600, or about 24%. The Central Midwives Board in its annual report speaks gravely of the shortage of practising midwives, stating that there are not enough of these women to staff properly the maternity institutions of the country, and many more are required for attendance on women confined in their own homes. That up to now there has been no serious deterioration in the standard of attention provided for the woman in childbirth is due to the devoted and self-sacrificing work of the midwives who are practising, but the decrease in their number, in the view of the Board, is now reaching such an acute stage that if adequate remedial action is not taken without delay there might be a breakdown in the maternity services. The position has been aggravated by the number of practising midwives who have been called away from maternity institutions for general nursing service with the armed Forces, though as some offset to this about 200 midwives have returned to practice after having retired on receiving compensation under the Midwives Act, 1936. But greater calls are being made on the midwifery service owing to the calling up of doctors and, in recent months, the rise in the birth rate. Not that there is any lack of pupil-midwives coming forward for training. The numbers who come forward would suffice for the proper staffing of the maternity service if all who completed the course practised as midwives afterwards, but only 58% of the women who enrolled as midwives in 1940 were practising as such in 1941. The others presumably found some other branch of nursing more attractive, though they considered it useful to hold the midwife's certificate. It is therefore not a question of lowering the educational or examinational standard, even if that were justifiable in any event. The C.M.B. is forced to the conclusion that a permanent solution to this problem can be achieved only by a substantial improvement in the general level of pay, in the conditions of service, and in the public regard for midwives. The appointment by the Minister of Health of the committee under the chairmanship of Lord Rushcliffe to review the salaries and conditions of service of practising midwives and pupil-midwives is welcomed whole-heartedly by the Board in the hope that some practical result may come about quickly.

LONELINESS IN INFANCY

While plans are being rapidly advanced for the accommodation of a quarter of a million little children in war nurseries it may be as well to take note of the observation that in infancy the loneliness involved in separation from home may be not only undesirable but lethal. In old age it is not uncommonly observed that when one of a happily married couple dies the other does not long survive. Dr. H. Bakwin (*Amer. J. Dis. Child.*, 1942, **63**, 30) suggests that the partnership of mother and infant may be no less vital, basing his conclusions upon observations made over a long period in the Bellevue Hospital, New York, and in other institutions. Twenty-five years ago the infant mortality rate in American foundling institutions was nearly 100%, and in the Bellevue Hospital about 40%. While an improved foster-home system lowered mortality, the failure of children to do well in hospital remained a problem. The "hospitalized" infant described by Dr. Bakwin sleeps less, passes more frequent stools, and is more subject to infections of the respiratory tract than his brethren at home. There is a marked dulling of reactivity to emotional stimuli: whereas babies of three months old, for example, normally smile in response to a friendly gesture, those in hospital fail to do so; they are listless and apathetic. There is a general lowering of resistance and delay or distortion in development. These symptoms cannot be accounted for by the illness which resulted in hospital admission, as the improvement on returning home is striking. At first the unsatisfactory progress of children in American hospitals was attributed to malnutrition; later, as nutritional standards improved, to cross-infection, nasopharyngitis succeeding malnutrition as the most frequent diagnosis. To lessen the danger of infections, the open ward was replaced by small cubicled rooms in which masked nurses and doctors moved cautiously lest they should stir up bacteria. Visiting parents were strictly excluded, and there was even devised a box in which a baby could be taken care of almost untouched by human hands. In spite of all these precautions the obstinate infants wilted in their cubicles and throve with humiliating promptitude when returned to their less hygienic homes. In desperation the paediatric policy was changed and mothering came to be regarded as essential in treatment. Interns and nurses were encouraged to pick up, cuddle, and play with their small patients, and parents' visits were welcomed. At the same time the infant mortality rate, which should logically have risen, fell sharply.

Although Dr. Bakwin refers especially to infants in hospital, he also stresses the unsatisfactory personality development in other institutions of children up to 4 years of age, his notes corresponding disturbingly with those of some observers in our wartime nurseries. Such children, especially if admitted before 2 years of age, find it hard to give or receive affection comfortably; enuresis or loss of bowel control is frequent, as are excessive egotism, aggressive behaviour or shyness, tempers, demanding of attention, finger sucking, and retarded speech. Obviously there are some admirable institutions in which these distress signals are comparatively rare, but it is no less obviously difficult to establish the perfect nursery in wartime, when the ideal staff is more than ever hard to find, and the demand enormously greater. The elderly hospital nurse who is too often in charge, with 15- to 18-year-old assistants as the bulk of her staff, is apt to look on the emotional needs of the small child as luxuries. Even those nurses and teachers who recognize the need for individual attention and tenderness are commonly too busy to supply the need. In day nurseries it is true that a child returns home each evening, but he is likely to find a mother too tired by long hours of war work to be loving and patient if the daily change from one environment to another makes him hard to handle, as well it may. Dr. Bakwin quotes a hospital case in which a child went steadily downhill until, "so weak that it seemed he might stop breathing at any minute," he returned the child to his mother, with the result of rapid and complete recovery. Such dramatic cases are presumably rare, but if, as seems established, the biologic unity of mother and little child cannot be disregarded with impunity, it is well to hesitate before supporting a policy that separates so many young children from their homes. It might even be better for the national effort to divert into the factories most of the large army of labour required to equip and maintain war nurseries and to leave the mothers to do the mothering of the "under fives." If this is not practicable, can we not have at least fewer and more motherly nursery homes?

War Medicine Series

The paper printed below is based on a lecture which was one of a series recently given at the British Postgraduate Medical School, Hammersmith

DYSENTERY AND DIARRHOEA IN WARTIME

BY

Sir P. H. MANSON-BAHR, C.M.G., D.S.O., M.D., F.R.C.P.

To parody Napoleon's famous dictum, "An army does not march, but may crawl, on its stomach." According to the Medical History of the war of 1914-18, bacillary dysentery took second place in importance among war diseases, and therefore it is up to us not to neglect the lessons taught. In this respect I think there is no need for us to repeat many of the mistakes that were made, some of which I will mention. Among those who directed the medical laboratory effort in that war were some who had had no previous experience of this problem, its many difficulties and pitfalls, so that we were fortunate to come out as well as we did on that occasion.

Classification of the Dysenteries

There is no such disease as "dysentery," and it no longer appears as such in Army and other returns. Dysentery connotes blood and mucus in the stools, diarrhoea, and abdominal colic. These appearances are produced by many different causes of ulceration or inflammation of the large intestine. One wonders sometimes why the Almighty in His wisdom created maladies so similar in their external and so dissimilar in their internal aspects as this group of "dysenteries."

We can classify it as follows: The first, the most important in wartime, is acute epidemic bacillary dysentery. It was of serious importance in operations in the Near and Far East; it was the main cause of the Gallipoli failure. No fewer than 120,000 casualties were evacuated from the Peninsula from July to November, 1915, and they were mostly due to bacillary dysentery, although other views commonly prevailed at that time.

It has been known as a very important war condition since Napoleon's retreat from Moscow; it was a factor, too, in 1870, in the South African War, and in many others.

The second group is the protozoal. This form, amoebic dysentery, on account of its more or less tropical distribution, appears to have attracted more attention than is its due. It is not the fatal disease that opinion supposes it to be. Amoebiasis is infection with *Entamoeba histolytica*; it is usually a chronic endemic disease. The complications are many because of the metastatic phenomena of this organism in its passage through the human body. Intestinal amoebiasis is originally the cause of hepatic or liver abscess; but *E. histolytica* is really a friend of man, endeavouring to live on the best of terms with him, and it is possible to harbour this parasite for the greater part of one's life without dire results.

Then there is a curiosity—*Balantidium coli*. This has been only once described in Great Britain, and that was in a mental patient, but it is said to occur among those who associate with pigs. Another form of dysentery is giardiasis (produced by *Giardia intestinalis*), a sort of spasmodic diarrhoea. It is extremely common in school children in this country, but has no real bearing upon the dysentery problem.

The next group is "helminthic dysentery," which is due to the Bilharzia genus of flukes. There is only one that is of vital importance—*Bilharzia mansoni*, named after Patrick Manson, who discovered it in 1903, and a common parasite of the Egyptian fellaheen. Since that time our knowledge of the life history of this parasite has become so complete and our methods of prevention so reliable that I do not think it is likely to figure in any future war. *Bilharzia haematobia*, in Upper Egypt and the Congo, may occasionally be the cause of dysentery; and in the Far East there is *Bilharzia japonica*, which, however, is much more a Chinese than a Japanese infection.

The differential diagnosis is very important, because in a country where we may encounter the whole gamut of dysenteries it is very necessary to distinguish one from the other. There are all these enigmatical forms of colitis which, when they occur in the tropics, are continually being ascribed to one or other of the better-known dysentery germs. I should put mucous colitis down as "sinner No. 1." It is common among business and intellectual people in this country, and very common in tropical countries as a manifestation secondary to bacillary dysentery.

Again, there is "ulcerative colitis," which is so common in this country at the present moment and is found also in most tropical countries. I do not think that this is a result of war, except that people who are being incessantly worried and bombed are more apt to reproduce this enigmatical disease, which is commonly associated with mental disturbances. In the last war I saw a number of people who suffered from symptoms of ulcerative colitis which lasted for some time, until the nervous shock passed off. It is extraordinarily like bacillary dysentery in its course and in the appearance of the mucous membrane when viewed through the sigmoidoscope. But it is really quite distinct from bacillary dysentery.

Next we have the great bogy of malignant disease. Carcinoma of the sigmoid flexure or rectum may give rise to blood and mucus in the stools, and because the patient is in the tropics or subtropics and passes blood and mucus in the stool his doctor very likely jumps to the conclusion that he has amoebic dysentery, especially if the stools contain Charcot-Leyden crystals, which tend to suggest amoebic origin. Malignant disease may give rise to this phenomenon and may simulate amoebic dysentery, but may also be a sequel to it.

Another condition to be considered is tuberculosis of the large intestine. This happens to be much more common in the tropics than in this country, and insemination of the tubercle bacilli in the mucous membrane, secondary to some other form of dysentery, takes place and is extremely difficult to differentiate except by sigmoidoscopic examination. Polyposis also produces blood and mucus in the stools; it has a Mendelian incidence, and nearly always terminates in malignant changes. The intestinal mucous membrane is studded with polypi, which resemble bunches of grapes. Simple polypus in children, especially in India and other endemic areas, is apt to be mistaken for one of the dysenteries. Digital or proctoscopic examination will often settle this point immediately.

Another condition which often produces blood and mucus in the stools in older men is diverticulitis: in those who complain of alternating diarrhoea and constipation and other uncomfortable phenomena it is advisable to keep this in mind.

Mercurial poisoning has also to be considered. Page and Wilson (*Lancet*, 1940, **1**, 640) recorded the occurrence of acute ulcerative colitis after cystoscopic examination of the bladder, the instruments having been washed in mercury oxycyanide. This has now been definitely proved to be due to mercurial poisoning; so that ulcerative colitis, which resembles that condition, may in reality represent an effort of the body to get rid of some toxin—not, of course, a metallic toxin—through the walls of the gut.

In the last war we had a lot of trouble, in differential diagnosis, with paratyphoid B, which is the cause of ulceration of the large intestine and blood and mucus in the stools. Subtertian malaria may produce an acute enteritis with intestinal haemorrhage and may be mistaken for amoebic dysentery. Another cause may be foreign bodies in the rectum or internal haemorrhoids, which may give rise to blood and mucus in the stools and be confounded with dysentery.

The Bacillary Dysenteries

Bacillary dysentery is a very large subject. Rather it should be called the "bacillary dysenteries." These occur in large epidemics; they have a seasonal distribution, and spread like wildfire. Epidemics of considerable magnitude often occur at the present day in Malaya, the Pacific islands, India, and Brazil. Nearly every new-comer to the tropics contracts bacillary dysentery at some time or other, children being especially susceptible. Bacillary dysentery is endemic in nearly every mental hospital, and thousands are spent year after year in order to prevent it.

Most bacilli of dysentery have now been found in this country. I myself have isolated Shiga's bacillus in London. This organism was discovered in 1898. It produces definite biochemical and serological reactions, it is a most important organism in war, and it is the one against which we require the most potent anti-Shiga serum—which has now been prepared. Next comes Flexner's bacillus, discovered in 1900. Since that time, however, it has been found not to be one organism, but many. Bacteriologists had been devoting some of their energies to splitting up this bacillus until, at the end of the last war, they had found a great many varieties. That, of course, is *reductio ad absurdum*; and since then much good work has been done on reclassification. Flexner's bacillus is now considered to consist of six antigenic varieties, all having a connecting link. The anti-Flexner serum on the market is prepared from these six varieties.

The last-comer in this series is Sonne's bacillus, discovered in 1915, and which until recently had been rather neglected. Sonne's bacillus ferments lactose slowly and is a common organism in this country. It sweeps the community in epidemic form, producing diarrhoea with blood and mucus in the stools or a syndrome resembling food-poisoning. It is now known to be the organism concerned in infantile diarrhoea and in many endemic fluxes in all tropical countries, but occasionally it may reproduce the dysenteric syndrome as severe as in Shiga infections.

The Shiga bacillus produces acid out of glucose; the Flexner group, acid out of mannite. They all give rise to specific agglutinins in the blood of injected animals. There are difficulties in serological diagnosis. Thus it is of no use in the acute stage of Shiga infections; one does sometimes get a high agglutinin content from about the third week of the disease onwards in titres of from 800 to 1,000. The Flexner group is not nearly such a good "performer"; and here the results are aways somewhat problematical, so that the only real value of serological diagnosis is in the chronic form of infection, in which the organism has produced chronic ulceration of the large intestine. In Sonne dysentery agglutination tests are usually more reliable. The stools are at first diarrhoeic and then mucus mingled with blood, resembling redcurrant jelly. The organisms are not always easy to isolate from the stools; they produce a sort of blue-grey colony, quite different from many other organisms on the plate that give rise to red colonies. Microscopical examination of the cellular exudate in the stools affords a rapid and ready means of diagnosis. The preponderating form of cell is the polymorphonuclear, but there are also large macrophage cells which closely resemble amoebae and cause considerable confusion. In acute bacillary dysentery with death within thirty-six hours of onset the mucous membrane is cherry-red and friable, and one can almost rend it in pieces like damp blotting-paper. The last four feet of the ileum and the whole of the large intestine from the ileocaecal valve down to the anal margin are in this condition. The next stage of coagulative necrosis is often very puzzling. These cases are known clinically as fulminating. Sometimes the necrosis is patchy and the appearance of the intestinal canal is that of islands of mucous membrane in a necrotic sea, and it is from these that regeneration eventually takes place. In the next stage the necrotic mucosa peels off like diphtheritic membrane. It is dead, and beneath it lies granulation tissue.

Difficulties in Diagnosis

The fact that dysentery bacilli disappear so quickly from the stools gives rise to difficulties in diagnosis. It enforces the plea that to work satisfactorily on these problems and to obtain rapid results and equally rapid cures we must place laboratories as near to the front as is possible, because when these cases arrive in a casualty clearing station or in a stationary hospital diagnosis can be rapidly made and measures be administered at the first possible moment so as to save the patient's life. An identity disk should be tied to the patient, stating that he has bacillary dysentery, and describing the treatment that has been given.

In microscopical sections a regular array of dysentery bacilli can be detected along the muscularis mucosae, and especially in the solitary follicles. Others taken later in the disease may show cystic degeneration of the mucous membrane, which is often a sequel to bacillary dysentery. An interesting point is the explanation of what is known as the "carrier state," in bacillary dysentery. Out of every hundred people affected about twenty become "carriers" for several months and the starting-point of fresh epidemics—for instance, they are considered to be the central point of every new outbreak of bacillary dysentery in India, and the bacilli persist in the mucous secretion of retention cysts in the bowel wall.

The appearance of the intestine in chronic bacillary dysentery is significant, reminding one of the cobblestones of some old French country town. It looks very much like chronic ulcerative colitis as encountered in this country, and has given rise to confusion between these two diseases. On taking cultures from these ulcers in the submucous sinuses the dysentery bacillus is usually found to be Flexner's. At one time thought to be a separate disease, chronic bacillary dysentery is one of the common causes of chronic diarrhoea in the tropics. It has been very difficult to know what to do in the way of effective treatment in such cases. In the last war the best results were forthcoming from surgical measures—appendicostomy or valvular caecostomy—but now sulphaguanidine is under trial.

Bacillary dysentery starts suddenly. It is an acute and toxic disease. Shiga's bacillus produces a virulent endotoxin, and the bacilli occur commonly only in the large intestine, but not in the blood stream, urine, or gall-bladder. Occasionally they have been isolated from the blood, but this is something of a fluke. They have also been found in the synovial exudate in dysenteric arthritis. A patient with acute bacillary dysentery usually has pyrexia. Therefore a dysentery with fever which commences suddenly is probably bacillary dysentery, and not amoebic, which is usually afebrile, as *E. histolytica* produces a cytolysin, but not a toxin. A patient with bacillary dysentery often vomits, but this does not take place in amoebic dysentery because it is not sufficiently acute. If the patient is a child, convulsions usher in the disease. These come first; later, blood and mucus appear in the stools.

After the initial diarrhoea blood-stained mucus is passed in quantities; generally the patient loses sphincteric control. Rectal tenesmus is very urgent, as is also dysuria, or painful micturition, due possibly to the spread of inflammation to the urinary bladder. The pulse is rapid and the tongue furred. Weight is lost at a tremendous rate, owing to dehydration. When the hand is placed on the abdomen the patient winces with pain: this degree of abdominal tenderness is never seen in amoebic dysentery. In bacillary dysentery one can palpate the spastic and contracted large intestine, which feels like a rubber band or tube: especially is this the case in the sigmoid colon, and it is acutely tender. In the more chronic forms of dysentery, particularly amoebic dysentery, there may be isolated tender areas, but there is not the generalized tenderness which is so characteristic of acute bacillary dysentery. The stools may vary from twelve to twenty-four in the day, or they may be uncountable. It is not correct to call them stools, but exudates, and often serum leaks out of the anus. What we should do then is to discard the bedpan and pack with tow; in that way many lives have been saved.

Forms of Bacillary Dysentery

Bacillary dysentery may be divided into mild, acute, toxic or fulminating, and chronic forms. In the mild one gets diarrhoea, which lasts for forty-eight hours, with blood and mucus; and Flexner's or Sonne's bacillus can usually be isolated. Shiga infections are as a rule much more severe; but I do not believe that even in Gallipoli the death rate was ever more than 10% of those attacked. In the Fiji Islands and the Solomons in former days death rates of 40 or 50% were recorded among the natives, who blame the Europeans for its introduction. The fulminating form is so acute that the patient may die within forty-eight to fifty-six hours from the commencement. The stools contain dark clotted blood possessing a peculiar musty odour, but when green sloughs are visible prognosis is serious. One of the fatal signs in bacillary dysentery is hiccup. I personally have never seen recovery in such a case. In children bacillary dysentery is an especially fatal disease, producing epileptiform convulsions, coma, and death.

Statistics regarding the geographical distribution of bacillary dysentery are often unreliable. For example, in one district of Central Africa statistics may record nothing but bacillary dysentery, and just a few miles away amoebic infections are said to predominate. Good and accurate statistics are returned by the British fighting Services, and there the two forms of dysentery are properly differentiated.

The great feature about bacillary dysentery is that it occurs in epidemics, which have a definite seasonal incidence. In North Africa, the Near East, and Iraq there are usually two epidemics during the year—one in the spring, and one, the more important, in the autumn, from August to November. There is also a good deal of evidence to show that bacillary dysentery is spread by house flies, and in their intestinal tract bacilli can be found; but there is no real evidence that it is carried by water, which appears to be the main vehicle of amoebic infection. There are milk-borne epidemics of Sonne infection in this country, but the starting-point in native communities is the carrier, and the passage of infection from one person to another by contact.

Complications of Bacillary Dysentery

The complications of bacillary dysentery are very characteristic. First of all conjunctivitis occurs about the tenth day, and iritis about the second week. There is also a dysenteric arthritis, which may be a poly- or a mono-arthritis. There may be synovial effusions, which begin suddenly, and all the joints of the body may be affected. The arthritis is often associated with pyrexia and rigors. It is curious that when the patient appears to be getting better and you think he is out of danger, then this sequel may make its appearance. Some observers say that they have seen hundreds of cases of bacillary dysentery and have never observed this; but it does not occur in every epidemic: in some the incidence is 25%. Sometimes dysenteric arthritis is confused with the gonorrhoeal form, which it somewhat resembles; but as a rule dysenteric cases clear up quickly and do not leave much disability behind. Then there is a dysenteric neuritis, and in the last war there was trouble with paroxysmal tachycardia, which occurred in convalescents and was probably due to the action of dysenteric toxins on the heart muscle.

(*The concluding part will appear in our next issue*)

RESEARCH IN THE U.S.S.R.

When the Germans attacked the Russians, the personnel of the U.S.S.R. Institute of Experimental Medicine gave up their long-term theoretical researches in favour of practical scientific problems. Last month they held a meeting, and Prof. Grashchenkov of the Moscow Neurological Clinic has cabled a brief report of the proceedings to this country. The main subjects discussed were the treatment of injuries of the nervous system and the control of certain epidemic diseases.

Treatment of Cerebral Lesions

Prof. Grashchenkov reported that in the last six months the neurosurgical clinic of the U.S.S.R. Institute of Experimental Medicine had treated 600 compound wounds of the head, in close collaboration with a mobile field hospital specially staffed and equipped, both surgically and radiologically, for neurosurgical work. As a result of this experience, Prof. Grashchenkov is strongly in favour of the use of sulphonamides. He recommends sulphanilamide, sulphapyridine, and sulphathiazole in varying mixtures and proportions depending on the variety of organisms disclosed on routine culture of the wounds. Brain abscess may supervene without at first giving rise to symptoms.

The treatment of aphasia and other focal brain lesions is carried out at a branch clinic of the Institute under Prof. Luria. Methods have been worked out for the restoration of normal functions. Prof. Kupalov, a pupil of Pavlov, considers that damage at the highest level interferes with the synthetic action of large areas of the cortex, with the production of torpor and neurotic complexes. Prof. Rosenthal, another pupil of Pavlov, has reported on the elaboration of temporary conditioned reflexes in a person with brain injuries. By means of this method he is trying to determine the degree of disturbance of the cortical processes and to estimate by the speed with which the temporary conditioned reflex develops the degree of recovery of function which may be expected. Other members of Pavlov's laboratory have employed prolonged sleep therapy by means of drugs, and have found this method particularly effective in cases of cerebral contusion. Details of the methods employed are not given in Prof. Grashchenkov's report.

Peripheral Nerve Lesions

Prof. Lavrentjev has studied various aspects of the regeneration of peripheral nerves and claims to have found evidence for the "chemico-motor role" of the peripheral segment in attracting nerve fibres to itself. Investigating the value of fixed pieces of spinal cord as transplants for bridging gaps after nerve lesions, he finds that the best results are obtained by using formalinized nerve, since this "quickly vascularizes itself and delays the proliferation of the connective fibrous elements of the scar." No details are given of functional recovery in animals or men after this procedure. The only means found for accelerating nervous regeneration was heat. For preventing the outgrowth of nerve fibres and the formation of neuromas Lavrentjev suggests ligation of the vessels of the nerve. Prof. Magnitsky presents a study of the chronaxie of peripheral nerve after full and partial disturbance of its functions. Prof. Orekhovich has studied the metabolism of degenerating and regenerating nerves and finds special histolytic enzymes at work during regeneration.

Louse-borne Typhus

Reports on investigations in infective diseases are of equal interest. Levkovich reported on the work, carried out at the laboratory of Prof. Smorodintsev, on the specific prevention and early diagnosis of typhus of the classical louse-borne type. For the first time it has been possible to carry out, in an epidemic area, a large-scale investigation of the effectiveness of a vaccine prepared according to a modification of the Weigl technique at the All-Union Institute of Experimental Medicine (it will be remembered that the original Weigl vaccine was prepared from the intestines of infected lice). At the same time the Cox vaccine, prepared from growths of *Rickettsia prowazeki* in the yolk sacs of developing fowl embryos, and treated with phenol and formalin, was tested under epidemic conditions. This vaccine had been supplied by the representatives of the American Red Cross. In animal experiments these vaccines were compared with the Durand-Sparrow vaccine made from the lungs of infected laboratory animals; it was established that the Cox vaccine is the most effective and the simplest to prepare.

In the same laboratory, work was carried out on the early diagnosis of typhus by means of a complement-fixation test performed at low temperature. This reaction is stated to be very sensitive and strictly specific, giving positive results as early as the first or second day of illness. The importance of such a result can hardly be over-estimated. Bengtson[1] in America has obtained positive results in endemic (flea-borne) typhus with a complement-fixation test in which she used as antigen a suspension of Rickettsiae; the reaction was positive as early as the sixth or seventh day of onset, and followed a course similar to that of the Weil-Felix reaction. A somewhat similar result was obtained in Q fever,[2] but these reactions were performed at 37° C. The earlier results in the Russian work are presumably due to the low temperature employed. These findings recall the work of Kahn,[3] who has found that the reaction which goes by his name is intensified if carried out at 1° C. In this case, however, Kahn considers that the strong reactions at low temperatures are of "general biologic type" rather than "syphilitic type." A fuller account of the Russian work will be awaited with interest.

Insecticides

Prof. Petrishcheva has investigated the possibility of using "local insecticide material" to be found in waste and cheap semi-processed products of the chemical industry and also in wild plants. Thus, for example, in one of the Siberian regions nearly 150 types of moss were found to have varying insecticidal powers, 50 of them in a high degree.

A number of insecticidal substances were tested against lice, and certain preparations were found to be highly effective when applied to clothing, or for the disinfestation of transport vehicles, including railway carriages. Details are not given in this communication, but Rossiysky[4] has previously written of the use of "nassecamoyad," a 10% solution of kerosene-carbolic soap, and of "solvent," a product of benzol and toluol, derived by fractional distillation and retaining their highest homologues. He states that the former destroys lice quickly and does not irritate the skin; its protective action lasts 2 to 4 days. The fumes of "solvent" destroy lice in 9 to 12 minutes; this substance causes, apparently, no harm to human skin. Russian workers have not recently made much reference to the heat treatment of clothing, but no doubt this is carried out, the latest researches having been directed towards the preparation of efficient insecticides. Chasovnikov[5] has written of the use of "solvent" in the field.

Treatment of Dysentery

Prof. Yermoleva reported on the use of lytic agents in intestinal disease. Bacteriophage has, of course, been used in bacillary dysentery for many years, notably by Compton[6] in Alexandria. The Russian contribution is the use of small amounts of sulphapyridine during phage treatment, and from this combination they report good results. Sulphapyridine treatment was described by Bobrovolskaia,[7] who gave it first to children suffering from dysentery in whom pneumonia was a complication. Its results were beneficial not only for the pneumonia but also for the dysenteric condition, and this finding led her to use it in uncomplicated cases, with excellent results. The dosage employed was small, not more than 0.7 g. being given in any one day, and the average total dosage being no more than 1.1 g. In other countries sulphapyridine, sulphathiazole, and especially sulphaguanidine are used in bacillary dysentery with striking success, but in larger doses than those quoted for sulphapyridine.

Other Researches

Prof. Khatanevel reported on a new method of rapid diagnosis in human tularaemia, which can be employed at an early stage of the disease and which can be used under field conditions. This author has written previously on the use of "tularin"[8] in early diagnosis; the test presumably depends upon a cutaneous reaction.

Prof. Tokin made an interesting report on a bactericide of plant origin. As a result of ten years' research with the help of a group of assistants he was able to establish that many plants have substantial bactericidal qualities, and that strong bactericidal principles are found in the ordinary turnip-like onion, garlic, radish, and probably in citrus plants. These bactericidal qualities are discernible in a vaporized state. Five, and in some cases three, minutes of the vapour of these plants is enough to inhibit and sometimes to kill certain organisms, such as streptococci and staphylococci and intestinal bacilli.

The Ministry of Health announces that, in view of the extreme shortage of rubber and the urgent need for conserving supplies for essential war requirements, it has been found necessary to restrict the sale of household rubber gloves to persons who are certified by a duly qualified medical practitioner to be suffering from (*a*) long and intractable eczema, or (*b*) cheiropompholyx, or (*c*) intractable dermatitis. Any person wishing to buy rubber gloves for such duties can do so only if her doctor certifies that she is suffering from one of these three conditions, and that the use of *household* rubber gloves is necessary for the performance of her household duties.

INDUSTRIAL HEALTH RESEARCH BOARD

The Medical Research Council has appointed the following to be the members of their Industrial Health Research Board during the period 1942-5: Earl De La Warr (*Chairman*), Prof. F. C. Bartlett, Brig.-Gen. A. C. Baylay, Dr. J. C. Bridge, Dr. A. N. Drury, Dr. T. Ferguson, Dr. M. W. Goldblatt, Dr. A. Bradford Hill, Dr. Donald Hunter, Prof. Esther Killick, Air Vice-Marshal Sir David Munro, and Mr. J. L. Smyth. Prof. A. W. M. Ellis, director of research in industrial medicine under the Council, will also attend all meetings. Dr. R. S. F. Schilling, one of H.M. Medical Inspectors of Factories, has been seconded to the service of the Council by the Ministry of Labour to act as secretary of the Board. The terms of reference of the Board have recently been revised and are now as follows:

> "To advise and assist the Medical Research Council in promoting scientific investigations into problems of health among workers, including occupational and environmental factors in the causation of ill-health and disease, and the relation of methods and conditions of work to the functions and efficiency of body and mind; and in making known such results of these researches as are capable of useful application to practical needs."

AWARD FOR GALLANTRY

Dr. ERNEST VICTOR NEWLING, medical officer in charge of a mobile unit, Civil Defence Casualty Service, Westminster, has been appointed an M.B.E. (Civil Division). The citation in a *Supplement* to the *London Gazette* dated Aug. 28 reads: "During air raids Dr. Newling has led his unit with gallantry and calm efficiency. On many occasions he has carried out the treatment of trapped casualties in most difficult conditions with complete disregard of danger from the possible further collapse of demolished buildings. By his prompt actions and skill Dr. Newling has saved many lives."

Correspondence

Lister Technique in Emergency Surgery

SIR,—There can be no doubt—as Prof. R. J. Willan wisely pleads (Sept. 5, p. 291)—that the young generation of surgeons should master the Lister technique. It would enable them to deal successfully with emergency surgery. Also there can be no doubt that many loopholes of infection can be blocked by the addition of the Lister technique to the highly skilled surgical technique in the strict aseptic surroundings in present usage. For example, a spray containing an antiseptic directed upon a plaster-of-Paris cast during its removal would stop dust and inhibit the growth of micro-organisms it might contain. The only reason for a separate room for this process would be the possible disagreeable smell of a carbolic spray in a general ward. Prof. Willan rightly scoffs at the absurd notion that antiseptics so damage tissues as to prevent healing and their ability to deal with infection. Those who correctly make so great a point of excising all dead and injured tissues do not seem to estimate the actual damage done to healthy tissues by the passage through them of the sharpest scalpel.

Many misconceptions exist at the present time about Lister's technique. He excised all dead tissues from the burns and compound fractures he had to treat. Many of us who assisted Lister in public and private (in fact, he left me in charge of his patients when he retired) are alive, and can testify that his wounds healed by first intention with the greatest regularity.—I am, etc.,

London, S.W.1 G. LENTHAL CHEATLE.

A Classification of Nerve Injuries

SIR,—I hope I shall not be thought critical of the excellent work which Prof. H. J. Seddon and his unit are doing on peripheral nerve injuries if I protest at the new terminology of which he is the foster-parent (Aug. 29, p. 237). He seeks to distinguish three states of a nerve: complete division, division of axis-cylinders without division of the nerve-sheath, and transient block. He proposes to call these "neurotmesis," "axonotmesis" (what a word! as Mr. Herbert would say), and "neurapraxia."

Our profession has suffered much at the hands of neologists, but even a helminth will turn. A new medical term should fulfil four requirements: it should be necessary, accurate, self-explanatory, and if possible euphonious. The most that can be said for these three is that the first two are accurate. "Neurapraxia" is the most objectionable, being actually misleading, since "apraxia" has for many years been the name of a psycho-physiological disturbance at the highest level. But why should we have to learn new words at all, when we can speak, in English, of "nerve-division," "nerve-contusion," and "nerve-concussion"?—I am, etc.,

London. W 1 W. RUSSELL BRAIN.

Prognostic Value of Blood Sedimentation Rate in Phthisis

SIR,—The paper by Drs. E. Lewis-Faning and M. Myers (Aug. 1, p. 125) on the prognostic value of the blood sedimentation rate (B.S.R.) in pulmonary tuberculosis is surely unreasonable in denying the value of serial tests in assessing the progress of the disease, while drawing important prognostic conclusions from a single test. A considerable volume of unpublished work at the Cheshire Joint Sanatorium points to the greater accuracy of conclusions drawn from serial results compared with those from a single test. Lynn, in an unpublished thesis, showed that the prognosis in patients with a fluctuating B.S.R. was almost as bad as in those with a rapid B.S.R., even though the final rate might be within normal limits. This work was carried further by Brooks, who showed that the prognosis was exceptionally good in patients discharged from the sanatorium with series of consecutive monthly B.S.R. readings within normal limits. The period of follow-up was six years.

I agree with the writers of the paper that B.S.R. estimation is not 100% accurate, but any case whose B.S.R. is not in keeping with the clinical and radiological condition is worth further investigation, as the following cases show:

1. A man with moderately advanced disease, in fairly good general condition, afebrile, and with a partially effective artificial pneumothorax, had a persistently very rapid B.S.R. (118–136 mm./2nd hour). On further investigation he was found to have a positive Wassermann reaction.
2. A girl was admitted with minimal tuberculosis. Her B.S.R. rose from 10 mm./2nd hour to 78 mm./2nd hour in three months. She was found to be pregnant, a fact she had succeeded in hiding until then.

A cold or a boil is commoner, but the increase in B.S.R. is less.

The cases with anomalously slow B.S.R. are rare, though there is a case in our recent records with radiological spread of disease accompanied by normal B.S.R. (including a normal sedimentin index). The few cases with positive sputum and normal B.S.R. seem to do well.—I am, etc.,

Cheshire Joint Sanatorium, Salop. A. CLARK PENMAN.

Megaloblastic Anaemia of Pregnancy and the Puerperium

SIR,—I wish to thank Prof. L. S. P. Davidson and Drs. L. J. Davis and J. Innes for their reply (Aug. 29, p. 256) to my comments (Aug. 15, p. 198) and for their elaboration of the grounds on which they base a diagnosis of a megaloblastic marrow reaction. If, as I understand from their letter, they include as megaloblasts not only the proerythroblast but also the megaloblast A of Israels, then I agree that where these latter cells were present in the cases quoted the diagnosis is justified. In my experience such marrows will also show megaloblasts B and C. I regret that my letter created the impression that I confine the term "megaloblast" to the haemoglobinated cell of Ehrlich. For the sake of brevity I included megaloblasts A, B, and C under the term "megaloblast series" in my diagram. All classifications of the erythroblasts must to some extent be arbitrary, for when does a boy become a man or, to use your correspondent's terminology, a megaloblast become a normoblast?

In fairness to Dr. Israels I must make it clear that he and I work at different centres, though in adjacent towns, and I deplore the exigencies of recent years which have prevented me from benefiting from direct personal tuition. I have adopted Dr. Israels's classification because I find it most useful in my own work and the least equivocal means of describing erythroblasts. In addition, it offers an explanation of the Ehrlich megaloblast and eliminates the description as "megaloblasts" of primitive red cells which may occur in significant numbers in normoblastic hyperplasias where deficiency of the liver factor plays no apparent part. On these grounds I regard the classification as both logical and practical and I should be glad to see it adopted as the standard terminology. In the meantime I feel that writers should "state their conventions" so that misunderstandings may be avoided.

I have no quarrel with the title "megaloblastic anaemia of pregnancy and the puerperium," which is obviously preferable to "pernicious anaemia of pregnancy." My doubts arise regarding the evidence on which certain of the cases are included as megaloblastic anaemias. If one could invariably infer the marrow reaction from the colour index, haematology would be much simpler but very much less interesting.

I have not studied the sternal marrow pictures of the few cases which have come my way where this type of anaemia was suspected. As treatment had already been instituted with both liver and iron, and recovery or partial recovery had taken place, sternal puncture seemed unlikely to be helpful. I have, however, seen one case following pregnancy with an initial high colour index progress to a normal blood picture on iron alone, after a brief course of liver in the early stages. I sincerely trust that no comment of mine will deter energetic treatment or cause any relaxation of vigilance until a normal blood count is restored and maintained.

Knowledge of these interesting and rare cases will be best forwarded if those in charge of obstetrical cases will, where possible, have a full haematological investigation carried out prior to commencing liver therapy if a megaloblastic anaemia is suspected.

In conclusion, I hope that no heat has been engendered by this exchange of correspondence. The doubts I have expressed arise from my interest in marrow interpretation and your correspondent's paper, and comments will be a stimulus to me in any future contact I may make with cases of this nature.—I am, etc.,

Manchester M. L. THOMSON.

Counter-measures in Prolonged Hypoglycaemia

SIR,—An outline of the counter-measures worked out by psychiatrists who daily, in the active treatment of mental illness, purposely induce insulin coma may be of practical value to the profession—see Dr. E. H. Roche's report on two fatal cases of hypoglycaemia (July 11, p. 35), and the recent correspondence on increase of hypoglycaemia (June 13, p. 739; June 27, p. 802; July 18, p. 80). In insulin coma therapy, failure to wake after administration of glucose occasionally happens, and the counter-measures equally apply to "ordinary" accidental hypoglycaemia, with the difference that while in coma therapy everything is at hand to meet the emergency, arrangements may have to be improvised in general practice.

1. Failure to wake after ingestion of glucose is not alarming when caused by deficient absorption from the intestinal tract; the condition immediately responds to intravenous glucose.
2. Failure to wake after intravenous glucose is not always alarming, since this may be due to inadequate quantities of intravenous glucose—i.e., due to hypoglycaemia proper. Large quantities, up to 250 c.cm. of the 33% solution, may be required, and hypoglycaemia may reappear unless a sugar depot has been made available by intestinal administration.
3. Failure to wake after adequate intravenous glucose is alarming, and here the term "hypoglycaemia" is a misnomer, since coma has passed from the hypoglycaemic stage to the post-hypoglycaemic stage—i.e., unconsciousness persists despite normal or increased blood-sugar levels. For example, Dr. Roche's first patient showed hyperglycaemia from 5 hours after the onset of coma until his death 7 days later; his second patient had hypoglycaemia proper during the 8 hours of his life after the onset of coma.

Abnormal persistence of cellular changes brought about during hypoglycaemia is the cause, and the treatment is to combat cardiovascular collapse and to facilitate the entrance of sugar into the brain cells. Further administration of glucose is contraindicated, and blood-sugar tests help to distinguish this condition from hypoglycaemia proper. Where these tests cannot be done, or be done in time, the response or partial response to, or the failure of, previous intravenous glucose points the way. The states of hypoglycaemia proper and of post-hypoglycaemia are not necessarily as clear-cut as outlined here, and no harm is done to refractory cases of hypoglycaemia proper by applying to them the first stages of the treatment for post-hypoglycaemia, which is as follows: (1) Continuous inhalation of 5% oxygen—CO_2, since the brain cells may not be able to utilize sugar unless provided with an excess of oxygen. (2) Injection of vitamin B seems to act in a similar way, and massive doses up to 25 mg.—e.g., one ampoule benerva forte—are given both intravenously and intramuscularly. Massive doses of adrenal cortical hormone (cortin, percorten, etc.), up to 10 c.cm., are also given both intravenously and intramuscularly, and intravenous injection of 10 c.cm. to 30 c.cm. calcium chloride is recommended. (3) To combat dehydration and haemoconcentration, 500 to 1,000 c.cm. physiological saline is given by intravenous injection. The stomach is washed out and saline left *in situ*; in the absence of saline tepid water may be used. (4) Lumbar puncture and the withdrawal of as much C.S.F. as will flow is the next step, the rationale being to reduce increased pressure and to draw off the sugar accumulated in the fluid—i.e., following the same reasoning as in narcotic poisoning. (5) If the foregoing measures fail, blood transfusion may still save the patient.—I am, etc.,

Mawnan Smith, Falmouth. H. PULLAR-STRECKER.

An Alphabet of Breast-feeding

SIR,—In his excellent article Prof. Charles McNeil draws attention to the waste of food involved by the substitution of artificial feeding for breast-feeding. But is the logic of this quite sound? A nursing mother will require more food on account of her lactation. I believe she is actually entitled to an additional pint of milk on the priority system. It is perhaps as well that a good cause should not be supported by an unreliable argument. Probably most of us will agree that far too many babies are weaned at an early age, and Prof. McNeil's article will be a great help to many of us.—I am, etc.,

Pleasington, near Blackburn. P. K. MUSPRATT.

Anaesthetic Death in the Surgery

SIR,—I appreciate very much indeed the comments and advice of Drs. P. E. Woodroofe and A. D. H. Simpson (Aug. 29, pp. 263 and 264) relating to my article "Anaesthetic Death in the Surgery." There are occasions, however, when the type of apparatus or anaesthetic as mentioned by Dr. Woodroofe is not available, or it is impossible to find even a colleague to attend, much less a qualified anaesthetist; this happens frequently in a country practice such as mine is. Moreover, most G.P.s only keep chloroform and ether for general anaesthesia, as a rule for maternity cases only. Had such a fatality occurred, a coroner's inquest, with a possible prosecution, would have been the only result possible, and most of us know the pitfalls that face an unfortunate member of the profession involved in such procedures.

Though we are given the licence to practise medicine, surgery, and midwifery, it seems that such responsibilities should not be undertaken, and the role of the G.P. must give way to specialization. Must initiative and enthusiasm be sacrificed on the altar of timidity? For there is not the slightest doubt that as the years roll by the responsibilities for surgical practice are lifted from the G.P., not by reason of his inability to cope with such conditions but by reasons created in prosecutions which (when voiced in the Press) naturally intimidate other G.P.s from accepting such responsibilities, capable as they are of attending to whatever the condition may be. This throws a great deal of work on the hospital staff, on whom such responsibilities seem to rest, and this situation is accepted by the public whatever the outcome. Instead of a capable, enthusiastic, and keen young doctor gaining experience if he sets his mind on general practice, he grows to fear any condition that might involve him in the courts. The form G.P.45 (Rev.) condemns him, and gives him an inferiority complex, even if he could perform the service necessary without having to produce such evidence as is required.

More encouragement and more adequate protection are necessary to produce, or rather bring out, the best in G.P.s, who, after all, are the backbone of the profession.

In conclusion, I should like to mention a paper that was brought to my notice since publishing my case, "The Role of the Epiglottis in Anaesthetic Deaths," by Mr. G. H. Caiger, F.R.C.S. This factor is not mentioned in any of the textbooks so far as I can gather, and is undoubtedly a very important one to be remembered. It was published in the *Journal of Laryngology and Otology* of May, 1942.—I am, etc.,

Maltby. A. H. BARTLEY.

"Removal for Mental Observation"

SIR,—While appreciating the motives which inspired Dr. Arthur Harris's article on the above subject (Aug. 1, p. 136), one feels that any deficiency in dealing with the type of case described lies not in the method adopted by the practitioner but in the facilities offered by the general hospitals for their reception. When mental symptoms are present relations are only too pleased to have the patient removed, whether it be "for mental observation" or otherwise. Not only is nursing at home impossible, but examination of the patient often equally so. Two cases seen recently exemplify these points.

Case 1. Male, *aet.* 26, ex all-in wrestler, with history of fractured skull 12 months before, locked his bedroom door and entrance could be obtained only by forcing the lock. He was lying on the floor, refused to answer any questions, and resisted vigorously any attempt to examine him. In the struggle I was fortunate to note one unequal pupil. Removal was imperative—but to a mental observation ward or to a general hospital? The latter was chosen, but after doing a lumbar puncture under light anaesthesia, no other examination being possible, he was removed "for mental observation" and subsequently diagnosed as G.P.I.; *but* he was removed before any diagnosis could be confirmed. His retention in a general ward was obviously out of the question.

Case 2. Female, *aet.* 44: restless, talkative, obstreperous. Examination quite impossible. History negative. Diagnosis, ? hypomania. Paraldehyde in the doses suggested by Dr. Harris was given with the greatest of difficulty. After being quiet for about 2 hours she was discovered fully clothed having a bath at 2 a.m. Nursing at home was out of the question and she was removed 'for mental observation" since no general hospital would have her.

The only way out of the difficulties enumerated by Dr. Harris would seem to be the provision of a mental observation ward in the general hospitals, staffed by nurses who are not afraid of mental cases as are the nursing staffs of most general hospitals, and where, given time and the facilities, organic nervous disease can be diagnosed when present.—I am, etc.,

London, N.6. W. LEES TEMPLETON.

Desert Sores

SIR,—Is it not possible that desert sores may be identical with the "boils and blains" inflicted upon the Egyptians in Biblical history, and that the condition may have been endemic in the Egyptian desert for thousands of years? It probably did not escape the observation of many doctors in general practice that a modified form of the same condition was prevalent in this country during last winter and spring. In my own practice the increase in cases of what may generally be described as "furunculosis" was very marked, and it seems that in some industrial towns in the Midlands it was also very prevalent. As a victim myself of successive crops (two or three lesions being present at a time) of a very unusual dermatosis, I may perhaps be allowed to attempt a description of it.

Usually starting as a small white-topped papule surrounded with a bright red areola and marked from the outset by its extreme painfulness, it gradually increased in diameter to the size of a halfpenny or even a penny. Nothing appeared to arrest its progress. Sometimes the skin was thinned out over it and almost transparent, while underneath was a purplish-blue exudate, due, presumably, to extravasated blood.

The ingestion of 50-mg. tablets of vitamin C made no impression, and when it was at its worst the advice of someone to try an injection of SUP 36 saved the situation so far as I was concerned; for I was at the time crawling round my practice with one of these lesions on each buttock. SUP 36, in fact, appeared to be a specific among a variety of other remedies tried. With the arrival of summer and an abundance of natural vitamin C in the form of tomatoes and black-currants further outbreaks ceased.

The condition described would appear, then, to be due to a lack of natural vitamin C, synthetic vitamin C having very little therapeutic effect. An increased permeability of the capillaries appears to be the result of this lack of natural vitamin C, and it seems to show that the vitamin alone is not the whole story in such conditions. It is possible, perhaps, that natural vitamin C has some principle loosely combined with it and acting as a sort of catalyst which has not yet been identified by chemists. The lack of citrus fruits during the last 1½ years has probably led to a gradually increased deficiency of natural vitamin C in the blood and brought about an increased proneness to such skin lesions. People of fair complexion, as noted in myself and a few others, appear, as Capt. H. M. Rapport notes (July 25, p. 96), to be more susceptible. Several months after the initial lesion a purplish-blue stain remains under the skin, the lesion itself receding only very slowly. The skin was never actually broken.—I am, etc.,

Hove G. L. DAVIES.

Tietze's Disease a Nutritional Deficiency?

SIR,—Among the many manifestations of subnutrition recently seen by us have been two cases of swelling of the costal cartilages, associated with weakness and lethargy, which conform to the description of Tietze's disease. Both cases have been investigated on the lines of Gill, Jones, and Pollak (*Journal*, Aug. 8, p. 155), with the same negative results. Estimations of the urinary excretion of vitamins have, however, given striking figures which support our view that this syndrome is not a disease *sui generis* but a local manifestation of malnutrition recognizable by deficiencies in vitamins C and B.

Case 1 was admitted to hospital, and the daily treatment in both cases was 700 mg. ascorbic acid and 2 drachms of baker's yeast incubated in a pint of peptolac. Daily estimations of urinary vitamin excretion serve to assess the degree of avitaminosis.

CASE 1 MRS. A, AGED 36

Leading Symptoms	Ascorbic Acid per 100 c.c. Urine*	Pyruvic Acid	B$_1$ Direct Estimation	B$_2$
Painful lump under right breast (6th, 7th, 8th costal cartilages). Lethargy, duration 1 year	mg. 0 0 10 20	mg. 4·75 2·7 3·0 2·0	 30γ 30γ 50γ 25γ	mg 0·25 0·2 0·2 0·2

Normal standards	2·5	0·8	100γ	0·30

* Estimations were made on successive days.

One general practice cannot provide sufficient material to support a theory of this kind, but other workers more fortunately placed may be persuaded to follow the clue.—We are, etc.,

GRIFFITH EVANS, F.R.C.S.
Caernarvon. ROBERT O. EAMES, F.I.C.

Renal Infarction and the Goldblatt Kidney

SIR,—The annotation on hypertension and unilateral kidney disease (July 18, p. 75) has stimulated interest in a disease syndrome which increasingly takes its toll as time goes on. The experimental work of Goldblatt has, as has been stated, found its clinical counterpart in a number of reported cases of unilateral kidney disease in which the hypertensive blood pressure has resolved itself following the removal of the injured organ. No reference has been made, however, to the more frequently occurring cases of embolic infarction of the kidney, observations on which might furnish valuable evidence in the investigation of arterial hypertension. A short résumé is given below of such a case seen in conjunction with Mr. Robert Mailer of Glasgow Victoria Infirmary.

The patient, a man aged 39, enjoyed good health until the onset of inguinal hernia. Blood-pressure readings approximated 140/90. During the third week after his operation the patient experienced pain in the left lumbar region, and this was followed by profuse haematuria. The condition was typical of embolic infarction of the kidney. Subjective symptoms included severe discomfort at the back of the head, vertigo, throbbing, precordial pain, and general malaise. Blood-pressure recordings showed readings of 220/140. The lumbar pain persisted for several days, and the haematuria for more than two weeks. Repeated blood-pressure estimations revealed a gradually diminishing tension, reaching its pristine level of 140/90 one month after the onset of the complication.

This case, in its pathology and symptomatology, constitutes the clinical analogue of Goldblatt's experimental clamping of the renal artery. It is here described by the courtesy of Mr. Robert Mailer.—I am, etc.,

Glasgow GEORGE KRASNER.

Bee Stings

SIR,—The article on bee stings by Dr. A. J. Jex-Blake (Aug. 29, p. 241) will interest many. Similar experiences obtain in South Africa. About 1926 a Pretoria tram was invaded by bees with disastrous results. One man was stung to death.

For some years I kept bees in the Free State. My experience and that of others was that many persons soon built up an immunity to stings. It was noted among some that failure to be stung at intervals meant loss of immunity. I have observed severe prostration after a single sting. Yet I have seen persons suffer hundreds of stings with little effect. Years ago I was the victim of such an experience in the Transvaal. Foolhardily I tackled a wild swarm without adequate protection. The invasion was summarily repelled. The drone of enemy planes seems as nought when compared with the hum of thousands of angry bees. A desperate run of nearly a mile ensued before the last attackers were shaken off. On my return journey I had a few more stings for luck. I was 14 years old at the time. My flight included a run down the boulder-strewn side of a steep kopje and at the bottom a clean and nimble leap over a four-foot fence. Years later I viewed the scene of the incident and recollected my accomplishments with astonishment. Well over 200 stings had to be removed from my face, neck, and arms. Despite a great shock of hair there were numerous stings in the scalp. I suffered no ill effect except much oedema of the face and intolerable itching.

Certain strains of South African bees are notoriously vicious, and it is remarkable the way they will wantonly attack persons or animals hundreds of yards away from the hive or nest. In East Africa the natives suspend the hives in trees. In the last war the Germans took advantage of this by shooting at the hives when attackers got within distance.—I am, etc.,

Cardiff. R. DRUMMOND.

Standardized Wassermann Reactions

SIR,—Dr. H. M. Hanschell's letter (Aug. 1, p. 141) makes depressing reading. His knowledge of complement-fixation tests must be scanty if he thinks that either the Ministry of Health or any other laboratory can send out complement standardized for use elsewhere. The value of this reagent depends on its interactions with the other components of the test and must be determined by each pathologist at the time he uses it. What the Ministry do guarantee is that the complement they send out is usable, and this is a most valuable aid to many laboratories.

With regard to dropping the Wassermann test in favour of precipitation tests, I personally do not agree. During the last 12 years I have performed an average of 7,000 Kahn tests a year, before which I had some training with Kahn himself when he was at St. Thomas's Hospital in 1928. In my hands this test is not so reliable as the Wassermann. It has some advantages—e.g., it becomes positive earlier than the Wassermann in primary syphilis—but I get too many false positive reactions, particularly in well-treated cases, for me to adopt it to the exclusion of the Wassermann. Nevertheless, I find it very useful as a confirmatory test. My experience with the Laughlen test was small, but it proved to be not so specific as the Kahn. Of all the precipitation reactions for syphilis (including the Kline reaction), I believe that the sigma test is the most reliable, but unfortunately it is too time-consuming and laborious for routine use. Thus "the tacit approval, by the Ministry, of Wassermann tests as performed by approved laboratories" seems to me to be the correct attitude, but I should like the required standard of work to be higher.

The thought of a medical officer in charge of patients, even if he has had first-hand experience of all laboratory tests, popping in to the laboratory to do a batch of tests if need be fills me with apprehension. Surely the foundation stone of accurate work with serum tests is regularity of performance. But this does not, and should not, exclude the pathologist from doing regular clinical work and thereby keeping in touch with patients. In short, the pathologist of a V.D. clinic should be a clinical pathologist.—I am, etc.,

L C.C. (Whitechapel) Clinic, E.1. I. N. ORPWOOD PRICE.

Lathyrism and Vitamin B$_1$ Deficiency

SIR,—At the close of your interesting annotation on "The Wernicke Syndrome and Vitamin B$_1$ Deficiency" (Aug. 29, p. 249) you suggest that antivitamin factors may prove to be the cause of other obscure nutritional diseases. A number of years ago, in collaboration with Lieut.-Col. L. A. P. Anderson, I.M.S., and Sir Albert Howard (*Ind. J. med. Res.*, 1924, 613), it was shown that lathyrism resulted most probably from the ingestion of foodstuffs prepared from the seeds of *Vicia sativa* var. *angustifolia*, and not, as had been assumed previously, from the seeds of *Lathyrus sativus*. The possibility of vitamin deficiency in the diet of the experimental animals was excluded, and we suggested that the disease was caused by the glucoside, vicine, or its aglucone, divicine, both of which were found experimentally to be toxic. It now seems to me to be more probable that vicine, or possibly some other constituent of the seeds of the vetch, inhibits the activity of aneurin or some other member of the vitamin B complex. It is hoped that someone more favourably placed than I now am may investigate the validity of this suggestion.—I am, etc.,

Bangor, N. Wales. J. L. SIMONSEN.

Draining the Ectopic

SIR,—There have been several accounts in the *Journal* (1942, **1**, 640, 669, 722) during the past few months of the delivery of ectopic pregnancies of viable age. In each case a drainage tube was introduced and in some was followed by a long period of invalidism. I wish therefore to call attention to the fact that, where the placenta cannot be removed entirely (sometimes a simple procedure), the abdominal wall can be sutured completely over the secundines without any fear of after-effects. The power of autolysis of the placenta is so great, and its connexion with the maternal blood supply so intimate, that it disappears after a few months. To introduce infection to it by means of a drainage tube will ensure a prolonged convalescence with fistula and adhesion formation. Pus, not placenta, discharges from the drainage tube. When a lithopaedion is discovered its placenta is non-existent.—I am, etc.,

FRANK STABLER,
Surgeon Commander, R N.V.R.

Self-medication and the Chemist's Shop

SIR,—Dr. E. L. Loewenthal's letter (Aug. 15, p. 199) was one of the most interesting and intelligent that has appeared in the *Journal* for some time. He hits one nail very squarely on the head when he writes, "The more effective the preparation the more dangerous it is . . . without medical supervision." To the examples he gives I would add a well-known cough syrup which will keep the cough under a very fair degree of control until cavities have appeared in the lung. I believe I am right in saying that we are now up against an enormously powerful vested interest, and that something like 90% of the patent medicines sold in this country are controlled from the financial end by one group.

The average chemist probably does not want to prescribe, and it is doubtful if he wants to "muscle in" on the territory of other branches of retail trade. But so long as the dispensing doctor continues to take away his legitimate dispensing trade he is left with but little option if he is to remain in business at all. One point, however, the would-be reformer must keep in mind. There has grown up in some parts of the country a belief or superstition that "doctor's medicine" has a magical superiority over any sold over the counter. Who in the profession that dispenses has not heard, "I thought it was time I had some doctor's medicine"? Again, there is a similar superstition that the chemist who does N.H.I. dispensing keeps only inferior drugs, and one's offer of a prescription may be refused on that ground.

Dr. Hermann Levy's statement (Aug. 29, p. 265) that "the English have a certain proneness" to self-medication is merely a statement of the truism that the English are a very gullible people. Possibly the real essence of democracy is that they should be permitted to continue to allow themselves to be gulled, but the profession in its fight against osteopaths, chiropractors, faith-healers, etc., has never shown any leaning towards that doctrine. One of the advantages of a State Medical Service is that we should be in a very much stronger position *vis-à-vis* those who make large fortunes by peddling to all and sundry drugs the capabilities of which are utterly unknown to them; another is that we should find ourselves freed from the necessity of competing with the chemist as retail tradesmen.

I wonder if Dr. Loewenthal is aware of the difficulty which the B.M.A. experienced in obtaining any newspaper publicity for *Secret Remedies* and its sequel.—I am, etc.,

DONALD M. O'CONNOR.

Hypnosis

SIR,—I thought your leading article on the present position of hypnosis (Sept. 5, p. 283) did not sufficiently stress one important point, in that the hypnotic state is related to the transference situation obtained in the preliminary stages of psycho-analysis. Psycho-analysis proceeds to render this situation conscious to the individual, whereas hypnosis does not generally do so. The point is that transference is proceeded with to obtain the necessary deeper analysis, whereas hypnosis serves to keep transference maintained, and builds up resistance to any deeper analysis. Jones mentions this in his book, *Papers on Psycho-analysis*. No doubt when a skilled psycho-analyst discovers his dream of paradise by securing as a patient a spiritualist medium suffering from hysteria, and endeavours to treat this entrancing combination by hypnosis, some further delectable expressions of opinion may obtain.—I am, etc.,

Tipton, Staffs. L. H. EUNSON.

Hyperostosis Frontalis Interna

SIR,—Dr. J. MacKay Crawford (Aug. 29, p. 261) is, of course, quite right and I apologize for the slip. The tolerance to glucose was reduced, not increased, in my case, as evidenced by the definite rise in blood sugar.—I am, etc.,

Truro. C. T. ANDREWS.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on August 28 the following medical degrees were conferred:

M D.—By proxy: E. W. Hart In person: W. A. Law

M B., B CHIR.—By proxy: P. Hugh-Jones, D. McAnally, G P. Baker, W. E. Church, H G. Danziger, G. E. Ffrench, H D. Juler, J. M. S. Knott, H. E. Lockhart-Mummery, L. H. H. May, J. C Waterlow, P. H. Buxton, P. M. Daniel, G. H. Dhenin, F. S. Glassow, A Hulme, R J Walker, B. G C. Ackner, P. F. Borrie, J. A. B. Gray, E. J. Holborow, H. W. F. Jones, T D. Kellock, D S. Short, J. F P. Skirmshire, J. C. Swanson, J. R. Thompson, T O Candler, A. G. Eddison, E J. Harrison, D. E. R Kelsey, A. Lyell, R. A. Palmer, S H Purser, D. L Sandes, J. F. R. Withycombe, W. B. Alexander, A. O Bech, J A. Black, N. F. Crofts, R. E Danckwerts, J. H L. Ferguson, J. L. Fluker, J. B. Foote, R. A. Holden, E. B. Jarrett, A. G. Leacock, C M. Phillips, P. M. M. Pritchard, J. H. B. M Rowlands, H D. Teare, J B Wyon, R. J. K. Brown, N. D. Compston, P. J. R. Deller, F. M. Lancaster, K. T. Lockhart, R. G Miller, E C. Poulton, E. G Sita, R. U Whitney, D. I Williams, C. D. Calnan, D G. R. Fox, J S. Pippard, J. R K. Preedy, F. S. Carter, G. F. Green, A. W N Oatway, T. O. Scudamore, R H Wheeler, J. Dean, R Dobson, H G McQuade, R. H. Meara, W. E S Bain, T. L. T. Lewis, D Rice, N L. Birkett, B F Brearley, E. G. A Crawshaw, J. A Peters, J. F. P. Quinton, P. K. Renshaw, J K. Wagstaff, R B Welbourn, M. R. Jeffrey, H M. Lawson, C. R Nash, H P Konig, L. R McLaren, J. J. Wild, and H. I. Winner In person: V. R. Arulanandom, N J. Goorney, H. M. J. Rowan, J. A. V. Bates, R. D. Sweet, I Macdonald, J. G. Salter, E.-C. E. Golden, W. S. S. Ladell, R W Danziger, and R. G. Mathers.

During July and August the titles of the degrees of M.B., B.Chir. were conferred on A. Bolton and Mrs. P. Eskell (Newnham College) and F. H Lomax and M. L. Macalister (Girton College), and of M.B on Mrs C. M Hall (Newnham).

UNIVERSITY OF LONDON

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN

The following scholarships have been awarded for 1942-3:

St. Dunstan's Medical Exhibition, Miss W. E. Lewington *St. Dunstan's Medical Exhibition (Supplementary),* Miss S Rollin *A. M Bird Entrance Scholarship,* Miss G Smith. *Mabel Sharman-Crawford Scholarship,* Miss P. J Lockley *Sir Owen Roberts Memorial Scholarship,* Miss E. J Harman. *A. M Bird Scholarship for Clinical Studies,* Miss M. E Townsend *Alfred Langton Scholarship,* Miss C. M. Watt. *Ellen Walker Bursary,* Miss E. T. Brash *Flora Murray Bursary,* Miss D. M Phillips. *Emma Beilby Bursary,* Miss H. B Hill and Miss E E Simpson *John Byron Bursary,* Miss D A Chapman and Miss B M Goetzee. *A M. Bird Postgraduate Scholarship in Pathology,* Miss F. D. Bosanquet, M B., B.S

Obituary

V. WARREN LOW, C.B., M.D., F.R.C.S.

The announcement of the death, which took place on September 2, of Mr. V. Warren Low will be received with regret by a wide circle of friends and colleagues. He was associated with St. Mary's Hospital during almost the whole of his career, first as a student, then as a member of the staff, rising to the position of senior surgeon, and afterwards as consulting surgeon and vice-president of the hospital.

Vincent Warren Low was born in 1867 at Staines and was educated at Cranleigh. After his training at St. Mary's he graduated M.B. at the University of London in 1892, and B.S. with first-class honours in 1893. In that year he became a Fellow of the Royal College of Surgeons, and two years later proceeded M D.Lond. At the outbreak of the Boer War he went out with the South African Field Force as a civil surgeon, served with distinction, and gained the Queen's medal and seven clasps. On returning he became assistant surgeon to the Royal Northern Hospital, and shortly afterwards assistant surgeon to St. Mary's, where in due course he became full surgeon and lecturer on surgery in the medical school. During the last war he was consulting surgeon to H.M. Forces in the Dardanelles and Egypt, with the temporary rank of colonel, A.M.S., and in that capacity again he did distinguished service for his country, was mentioned in dispatches, and was made Commander of the Bath.

The Royal College of Surgeons claimed a great deal of Low's interest for many years. From 1916 onwards he was a member of its Council and from 1928 to 1939 a Vice-President. He served the College as a member of the Court of Examiners, and he was also at various times examiner in surgery to the universities of Cambridge, London, and Liverpool. For some years he was a member of the University of London Senate. He could be described as a great "hospital man"; he was a member of the Council of the King Edward's Hospital Fund for London, and consulting surgeon to several cottage hospitals in the metropolitan area. Another institution in which he was greatly interested was the Royal Seabathing Hospital at Margate, of whose committee of management he was a valued member. An important office he held for many years was that of chief consulting surgeon to the L.M.S. Railway Company.

In medical society life Warren Low was always a popular figure. He was not a brilliant or frequent speaker, but he was a great listener, even after partial deafness had robbed the meetings of some of their interest for him. His countenance continued to radiate cheerfulness, even in his later years of disability, and his humorous turn of speech, often in the vein of happy reminiscence, made his rare interventions either in business or scientific discussion always welcome. He was an old member of the Medical Society of London; his first contribution to its *Transactions* appeared more than forty years ago. Eventually he became one of the trustees of that society and as far back as 1919 its president. He was also prominent in the Royal Society of Medicine and was its president in 1932-4. He had previously been president of the Section of Surgery. His old students have occasion to remember with gratitude the excellence of his teaching, but he attempted no ambitious writing. He was prominent in the Masonic fraternity, a Past Master of the Sancta Maria Lodge attached to St. Mary's Hospital, and a member of the United Grand Lodge of England. He was also president of the Society for the Relief of Widows and Orphans of Medical Men. He was Junior Warden of the Society of Apothecaries, which he joined in 1914 and in which he took great interest, not having missed a single meeting of the Private or Full Court after becoming an Assistant.

DAVID WATERSTON, M.D., F.R.C.S.ED.

We regret to announce the death of Prof. David Waterston, which took place on Sept. 4 in Edinburgh at the age of 70. He had held the Bute Professorship of Anatomy at St. Andrews for 28 years.

Waterston was born in Glasgow, the son of the Rev. Richard Waterston, for many years Free Church minister in Dundee. He studied medicine in Edinburgh and graduated M.A. in 1891, M.B., C.M. with honours in 1895, and M.D. with gold medal in 1900; he took the F.R.C.S.Ed. in 1898 and in later life was elected F.R.S.Ed. For twelve years he was demonstrator of anatomy at Edinburgh University and he held the Crichton Research Fellowship in anatomy for three years. In 1909 he became professor of anatomy at King's College, London, resigning in 1914 on his election to the chair at St. Andrews. He was Arris and Gale lecturer at the Royal College of Surgeons of England in 1914-15 and Struthers Memorial Lecturer at the Royal College of Surgeons of Edinburgh in 1927. He represented St. Andrews University on the General Medical Council for ten years and served also for some time as a member of the Dental Board. He joined the British Medical Association in 1898, and was vice-president of the Section of Anatomy in 1906 and of the Section of Anatomy and Anthropology in 1939. At the Bournemouth Annual Meeting he opened a discussion on the mechanism of pain, and the text of his paper was published in the *British Medical Journal* of December 15, 1934.

Waterston was deeply versed in his own subject, and his reputation as a teacher was high. He was the author of *Anatomy in the Living Model,* which embodied his Arris and Gale lectures, and edited the *Edinburgh Stereoscopic Atlas of Anatomy*; he also contributed papers on anthropology, embryology, and comparative anatomy to scientific journals and the publications of scientific societies. He was one of the pillars of the James Mackenzie Institute for Clinical Research from the time of its foundation at St. Andrews and acted as its honorary consultant; he also served on the local town council, and was a well-known figure on the links of the Royal and Ancient Club. A memorial service was held on Sept. 9 in the University Chapel, St. Andrews.

The Services

The King has approved the following appointments and awards in recognition of gallant and distinguished services in the Middle East during the period Nov., 1941, to April, 1942.—*C.B.E. (Military Division)*.—Acting Brigadier G. F. Allison, M.C., late R.A.M.C.; Temp. Brigadier J. Walker, M.C., late R.A.M.C. *O.B.E. (Military Division)*.—Acting Brigadier R. R. G. Atkins, M.C., R.A.M.C.; Temp. Cols. J. S. K. Boyd, H. V. Leigh, G. S. McConkey, and R. F. Walker, M.C., R.A.M.C.; Major (Temp. Lieut.-Col.) K. Fletcher-Barrett, R.A.M.C. *M.B.E. (Military Division)*.—Capts. (Temp. Majors) P. B. Ascroft, W. A. Oliver, L. S. Rogers, and H. B. Stallard, R.A.M.C. *M.C.* —Capt. (Temp. Major) E. F. S. Morrison, R.A.M.C.; Capts. R. D. D. Birdwood and V. Rangachari, I.M.S.

Mentions in Dispatches.—Capt. (Temp. Major) R. A. Smart, R.A.M.C.; Major (Temp. Lieut.-Col.) H. W. Mulligan, I.M.S.

Temp. Surg. Lieut.-Cmdr. H. G. Rees, R.N.V.R., has been appointed an O.B.E. (Military Division) and Temp. Surg. Lieuts. P. W. Isaac and C. H. F. Wood, R.N.V.R., M.B.E. (Military Division) for endurance and devotion to duty when H.M.S. *Cornwall* and H.M.S. *Dorsetshire* were sunk by Japanese air attacks in the Indian Ocean.

The D.S.C. has been awarded to Surg. Lieut.-Cmdr. B. S. Lewis, R.N., for gallantry in an action which resulted in the safe passage to Malta of an important convoy, and Surg. Lieut. G. N. Reed, R.N., and Temp. Surg. Lieut. R. R. Wethered, R.N.V.R., have been mentioned in dispatches.

The D.S.C. has been awarded to Surg. Cmdr. L. Lockwood, R.A.N., for bravery and endurance when H.M.A.S. *Hobart* was taking convoys across the China and Java Seas in the face of sustained enemy air attacks.

Medical News

At a sessional meeting of the Royal Sanitary Institute to be held at Oldham Town Hall on Sat., Sept. 26, Dr. E. R. Peirce will read a paper on "The Control of Sea- and Air-borne Disease."

The Medical Research Council invites applications from medically qualified women for a studentship for training in methods of experimental psychology; preference will be given to candidates who have had some special training in physiology or neurology, or who have already had some experience in the use of research methods. The studentship will be tenable for six months, during which the holder will receive training under the direction of Prof. F. C. Bartlett at Cambridge. Payment will be at the rate of £350 per annum, and the student will be expected to give her whole time to the work. The award will be made with a view to possible opportunities for research into problems arising during the war, either in the Services or in industry, but no definite promise of employment after the expiry of the studentship can be given. Applications should be lodged with the Secretary, Medical Research Council, c/o London School of Hygiene, Keppel Street, London, W.C.1, by Oct. 5. Forms for the purpose will be supplied on request.

Sir Stanley Woodwark, M.D., F.R.C.P., has been elected Master of the Barbers Company. He has also been re-elected for a further year to be Master of the Society of Apothecaries. The famous Hall of the Barbers Company, which survived the Great Fire of London in 1666, was destroyed by the air raid on London at the end of December, 1940. Mr. John Howell Evans, F.R.C.S., has been elected Renter Warden of the Barbers Company.

Dr. James Aubrey Ireland of Shrewsbury has been elected an Alderman of the Salop County Council

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* a further large rise in the incidence of measles, 924 cases, occurred during the week. A small drop, 23 cases, was recorded for whooping-cough. The notifications of scarlet fever, diphtheria, and dysentery rose by 123, 88, and 32 respectively. In the case of diphtheria this trend was fairly general throughout the country, the only county with an appreciable increase being Lancashire, with 27 cases more than in the preceding week.

The largest rises for scarlet fever were in Lancashire 27, Yorks West Riding 25, Staffordshire 19, and Wales 27.

Of the 18 notified cases of typhoid 9 occurred in Buckinghamshire, Aylesbury R.D.

Whooping-cough showed considerable fluctuations. The largest deviations were a drop of 34 cases in London and a rise of 32 in Lancashire.

The higher incidence of dysentery, 32 cases, was due to small widely dispersed outbreaks. The only local outbreaks of any size were those of Shropshire, Oswestry R.D. 9 cases, and Glamorgan, Pontypridd U.D. 8.

In *Scotland* during the week there were 338 cases of scarlet fever, an increase of 66. The largest of the local rises was in Edinburgh—53 cases, compared with 29 in the preceding week. The increase in the incidence of dysentery, from 69 to 86 cases, was due to outbreaks in the Northern and North-Eastern areas; in the counties of Zetland, Kincardine, and Aberdeen there were 13, 14, and 14 cases respectively.

In *Eire* returns included a case of typhus fever notified in the Rural District of Kanturk, Co. Cork.

Whooping-cough

The possibility of controlling whooping-cough by inoculation is being actively pursued. This disease is the most deadly of infectious diseases among infants. During the five years before the war the numbers of children under 1 year of age dying from the principal infectious diseases of childhood were: whooping-cough 4,196, measles 2,212, diphtheria 380, and scarlet fever 80. It is announced in the September issue of the *Monthly Bulletin* of the Emergency Public Health Laboratory Service that the effectiveness of pertussis vaccine for immunization is to be investigated by a large-scale field experiment. The trial is to be made with children aged 6 months to 3 years, who are to be kept under observation for at least one year. The results obtained will be compared with a control series of similar age and living under the same environmental conditions.

Returns for the Week Ending September 5

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,472, whooping-cough 1,197, diphtheria 787, measles 3,024, acute pneumonia 379, cerebrospinal fever 73, acute poliomyelitis 24, dysentery 112, paratyphoid 13, and typhoid 7.

No. 34

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 27.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

QUERIES AND ANSWERS

Aspirin for Asthma

A. K (Manchester) writes: I have a lady patient, aged 64 years, with bronchial asthma of many years' standing. She tells me 2½ gr. of aspirin gives her 36 to 48 hours' immunity from wheezing and she sleeps all through the night. Occasionally she takes only 1¼ gr. of aspirin to produce the desired result. Is there any pharmacological explanation in support of her findings? She assures me it has never failed her

Auscultation in Non-penetrating Abdominal Injuries

Dr. F. PIERCE HUDSON (Liverpool) writes: Dr H. P. Tait, who inquires about the value of auscultation as an aid in the diagnosis of non-penetrating abdominal injuries (Sept. 5, p. 300), may be interested in the following case I encountered last week. A girl of 2 years was admitted to hospital 7 hours after falling down some stairs. She was very severely shocked. Her general condition and the difficulty of diagnosis delayed operation for 24 hours. On three occasions before operation I auscultated her abdomen and heard peristaltic movements in all areas. At operation the small bowel was found to be ruptured in two places and there was general peritonitis

Blood Injection in Tuberculosis

Dr. B. JUHN (Kenton) writes in reply to Dr. J. H. Fletcher (Aug. 22, p. 236): Since Wassermann's and Neufeld's papers about immunity in tuberculosis there were not many new discoveries in this very difficult field. Besides the different strains of the tubercle bacillus the tissue allergy and the tissue immunity play a very important role. Although active immunity will be the aim in the prevention and cure of tuberculosis, numerous sera for passive immunization were tried (Maragliano, Marmorek, Koch, Behring) without success. According to C. Spengler the protective bodies against tuberculosis are not present in the serum but in the red blood corpuscles. His preparation "I.K" was obtained from erythrocytes. It was completely ineffective. Although the humoral immunity plays certainly a smaller part in prevention and cure of tuberculosis than the cellular, I tried repeated blood transfusions in cases of exudative tuberculosis, the donors being cases of healed fibroid tuberculosis The number of cases so treated is too small to be conclusive.

LETTERS, NOTES, ETC.

Apple, Pear, and Carrot Treacle

Dr. E. H. STRANGE (Stamford Hill, N.16) writes: May I draw the attention of practitioners in country districts and of those supervising factories with canteens to a very valuable national source of food often allowed to go to waste? Inferior varieties of apples and pears, and those affected by the attack of the codlin moth and the saw-fly, as well as those of poor keeping qualities, are allowed to rot in this country in enormous quantities. These can be converted into "treacle," a superb flavouring and sweetening agent. Before the war "apple treacle" was eagerly bought up by confectioners at about 10s. a gallon. It can be used to sweeten and flavour almost all sweet dishes, and an expert cook with a supply can make a whole series of sweets hitherto unknown to her patrons and of the highest quality. The treacle produced by perry pears is scarcely distinguishable from that obtained from apples, but that from better varieties of pears should be so much the more exquisitely flavoured. The production of treacle from apples and pears is not a job for the housewife or the amateur, but it is done at a very reasonable cost by firms who make a specialty of this sort of work. The yield for average inferior sorts of apples is about 15 gallons a ton of fruit, and the cost of processing is quoted per ton. It ought not to be difficult in country districts to get together such quantities of apples and pears if one bears in mind that fruit for this purpose need not be of high quality or completely sound and whole. Treacle from carrots can be prepared, though the flavour is not nearly so pleasing, and it does not keep so well as that from apples and pears. At one time this spring carrots not of first quality could be bought at 50s. a ton. Such carrots would have paid handsomely for treacling

Bleeding Tooth Sockets

Dr. J. T. MACLACHLAN (Dornoch) writes: During the last 50 years I have been twice called out of bed to stop bleeding tooth sockets. The usual styptics—iron, tannic acid, etc.—have failed in my hands to do so; and I have been obliged to plug the socket of the bleeding tooth with cotton-wool and to insert a horseshoe pad of Gamgee tissue between the teeth and tie the jaws together. This proved successful. The two interesting cases of bleeding after tooth extraction reported by Dr. G. E. H. Le Fanu (Aug. 15, p. 208), which were promptly cured by inserting a pencil of silver nitrate, will be greatly appreciated by practitioners. In a similar manner I have on one occasion stopped a bleeding nose, where the blood was spurting yards from the patient, by touching the bleeding-point on the septum with a caustic—silver nitrate. Recently I saw a man who had been struck on the mouth with the head of a golf club, displacing some teeth and lacerating the lower gum. In this case the few styptics that were available failed to stop the persisting welling-up of blood into the mouth, and I was compelled to use pads of cotton-wool in front, behind, and between the teeth, and to tie the jaws together. Prof. Grey Turner (Aug. 29, p. 258) has drawn attention to the valuable styptic power of turpentine in bleeding tooth sockets. Erichsen, in his classical work on surgery, drew attention to the great value of turpentine as a styptic; and he mentions a case of persistent bleeding from the tonsil that was successfully treated by a gargle of turpentine.

MEDICINE 100 YEARS AGO

Extract from a leading article in the *Provincial Medical Journal,* September 17, 1842:

"It appears, from the account which the *Times* gives of the accident and inquest, that the bodies of Burke and Carrol [two of four boys who had been exposed for several hours during the night to gases escaping from a lime kiln], being found deprived of circulation and respiration, were looked upon as quite beyond recovery, and no effort whatever was made to restore them to life. Now this was unquestionably a most unfortunate blunder, one which shows clearly, how dangerous it is that a practitioner should take the responsibility of cases, of such rare occurrence in this country, without availing himself of the advice of some gentleman, whose experience and knowledge of medical jurisprudence render it impossible that such an unlucky omission could occur.

"It is well known to persons skilled in legal medicine that, under proper treatment, persons recover from the deleterious effects of carbonic acid after many hours of exposure to the gas, and even after many hours' suspension of the circulation and respiratory movements, and it is laid down as a principle, that we should never despair of restoring animation until cadaveric rigidity is unequivocally established. If the limbs continue flexible, respiration should be imitated unceasingly for several hours (or until the occurrence of rigidity), by pressure made about twenty times in the minute upon the abdomen in the direction of the diaphragm, and simultaneously on the chest in the direction of the spine; these compressions should be assisted by the process called by the French, aspiration, which consists in *drawing air from the lungs* through a nostril-tube, and may be executed by the mouth of an assistant or by Weiss' stomach pump; thus a certain quantity of air will be withdrawn from the cavity of the chest about sixteen times in the minute, and an equal quantity of fresh atmospheric air drawn in when the capacity of the thorax is restored by natural elasticity. At the same time constant efforts should be made to stimulate the respiratory muscles, by galvanism, by the occasional dashing against the body of cold water if its temperature be natural, hot water (at 100° or 102°) if the temperature of the body be reduced, by careful drying and diligent friction after each affusion, and finally by flagellation, which proved so advantageous lately in a case of asphyxia from drowning reported by Dr. Ogier Ward, of Wolverhampton."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY SEPTEMBER 26 1942

THE BRITISH TRADITION AND THE NEW OUTLOOK*

BY

Sir BECKWITH WHITEHOUSE, M.S., F.R.C.S., F.R.C.O.G., F.A.C.S.(Hon.)

President of the British Medical Association

Presidential addresses to the British Medical Association in the past have covered a very wide field. Some have been purely scientific; others have been retrospective; and yet others medico-political. My words to you to-day are not scientific; perhaps they are not progressive. They are rather an appeal to retain, in this uneasy world of change and planning, those traditional elements upon which the sound rock of British medicine has evolved and been built. What is this rock, so stable that it is the envy of other nations? It is, I am sure, that indefinable but intimate relationship which exists between the patient and his doctor. In this island of ours the family doctor has been for years, and still is, the bulwark upon which much of the happiness of the people so largely depends. He is not so much a prescriber of pills and mixtures as a psychotherapist and adviser, a confidant and trusted friend.

You know full well the problems, moral and sometimes spiritual, that come before all of us in our daily work. As a gynaecologist, perhaps I hear an undue proportion of people's worries that cannot in any way be classified as scientific medicine. What I have learnt to appreciate more than anything else during thirty-odd years of practice is the unclassified and officially unrecognized work that every day is performed by the family doctors of the British Isles.

A few weeks ago I was in the consulting-room of a medical man whose practice extends over a large rural area in the West Country. It was not a large consulting-room, but it was well equipped with the modern essentials for accurate diagnosis, and it was situated in a tiny country village overlooking the Wye Valley. My eye caught an illuminated framed address, and I asked the doctor's permission to read to you to-day a few sentences of that address. This is what it said:

> "It is now seven years since you first came among us, and your patients and friends desire to take advantage of the opportunity thus afforded to present you with some tangible proof of their fullest appreciation of your great skill and untiring devotion in the exercise of your profession among all classes of the community in which you practise. To say that the poorer among us are some of your most grateful patients is at once a tribute to your honour and a source of admiration for you on the part of us all. We hope and trust that you will continue your beneficial work among us for very many years to come."

How many consulting-rooms in this country contain such testimonials? Perhaps not many, but well I know that the spirit is there, if not expressed. It is the "aura" that pervades the private sanctum of most family doctors where private and domestic secrets are exposed and discussed, and honest advice is given in the confidence that is enjoyed only by the sister professions of the Church and the Law. It is the essence of our British medical tradition.

My mind goes back to another experience. I was seated a few years ago in the large, perfectly equipped operating theatre of a State hospital in Utrecht. The surgeon, a salaried State professor, was performing an abdominal operation that is almost a daily occurrence in any large gynaecological clinic. The technique of surgeon and assistants was good, and the panoply of surgical ritual evident in all its detail. What impressed me, however, was the extreme length of the incision, which seemed to extend over the whole abdomen. At the close of the operation I sought the reason for this apparent "furor operandi." I was informed that the length of incision was to provide a good view for the audience at the back!

I could add other side-lights on the inner working of various State-controlled European hospitals, where the gods of science and technique, efficiency and statistics, override other considerations; but this incident will suffice to indicate some shortcomings of a system which perhaps some would like to see installed in this country. Social changes may be sudden and catastrophic, but more generally they are insidious in both their onset and their development. Medicine in Britain, so far as its practice is concerned, has been undergoing a slow major revolution during the last quarter of a century. The Ministry of Health, founded soon after the last war, and the legitimate child of the British Medical Association, was the concrete organic expression of those who recognized the importance to the nation of preventive as opposed to curative medicine.

The Traditional Link in British Medicine

While recognizing the necessity for a co-ordinating body, and admitting the immense services which the Ministry has contributed to the nation's health, I have viewed with some apprehension the inroads which have been made in recent years upon the influence of that traditional link of British medicine, the family doctor and his patient, and the swing towards State medicine. The bond between the Ministry of Health and the various health services administered by the local public health authorities is growing, communal services are increasing, and we may awake one day soon to find ourselves members of a co-ordinated State health service. I am convinced that neither the people of this country nor the bulk of the medical profession desire to become the regimented units of a system of bureaucratic control. The average man and woman to-day have very definite views about what they want in matters of health. They naturally desire efficient treatment, and they know what efficient treatment is and what it means. At the same time, the British public at heart dislikes communal methods of treatment, however efficient they are. How often does a patient on return from a visit to a public clinic say, "Well, I think that I will see him privately next time, and then I shall really know something"? This may be wrong in theory, but it is very true in practice.

During the present meeting we have been considering the Interim Report of the Medical Planning Commission. The report has already reached the general public, and it is interesting to note the reactions of the man in the street to the reforms which the Commission suggests. In a well-known women's paper I recently noted the following:

> "'Group Medicine,' as advocated by the Medical Planning Council, means that private practice as we know it to-day will be more or less abolished, and that teams of doctors will be housed in Health Centres—a network of which will cover the country. To those of us who value a personal relationship with a doctor we have known and trusted for years, this scheme may seem disturbing."

---

* Presidential Address delivered at the Annual General Meeting, Sept. 9, 1942.

This opinion is not isolated. Indeed, the view is gaining ground, both within and without the profession, that after the war medical practice, as we know it, will be no more. Personally, I do not believe that this will be so. Certain changes there will be—indeed, there must be; but so long as Clauses 24 and 26 in the Planning Commission's Interim Report are accepted as the foundation upon which all reforms are built the British tradition is likely to be maintained and strengthened. It is a healthy sign that criticism from the lay side is mainly concerned with this basic principle.

If, in all future discussion and legislation designed for the betterment of the national health, the sacred bond which exists in Britain between the doctor and his patient is not lost or indeed broken, then, in my opinion, the main suggestions of the Planning Commission can bring nothing but good to the community, and it should be our duty to implement the proposals with a willing acquiescence if and when we are asked to do so. The alternative, as I see it, is a system of salaried State medical service, which I believe to be detrimental to the national health and the personal interests of patient and doctor alike.

The Stimulus of Competition

The idea of working for a fixed salary has always been distasteful to me. It eliminates competition, it stultifies individual effort, and therefore is a bar to progress. Competition there must be; otherwise the stimulus to increased effort is removed, and the spice of life loses something of its piquancy. The active and progressive mind is not content to say, "So far and no farther," and a salaried post, however good, is not satisfying. We see this in all walks of life, and perhaps at no time better than the present. High and, in some cases, grossly exorbitant wages are being paid in industry in a misguided attempt to stimulate production. Fixed hours and high wages have not been followed by increased output. We see reports in certain industries of falling output due to "absenteeism." The well-paid and possibly tired worker, with no other stimulus to increased production than the verbal lash of the Government's or the union's mouthpiece, sits back in his chair and takes a day off. Human nature is the same in all occupations and all grades of society. Remove the stimulus for individual effort by limiting the individual's capacity for personal betterment, and a brake is applied to progress. We see the principle recognized even in Russia to-day, where 25 years after the establishment of the Soviet's "New Order" personal "rewards" in money or goods are awarded for outstanding individual service.

In our work exactly the same arguments apply. The medical profession is not a rich community in terms of the acquisition of this world's goods. It never has been and probably never will be. Nevertheless, the spirit of competition exists among us. It is a thoroughly desirable principle, and one which should not be suppressed. We see its application in several ways. Even among the whole-time Chairs at our universities, both pre-clinical and clinical, competition occurs when a Chair with a higher salary falls vacant. The university with its underpaid Chair may lose its scientific professor to its more opulent sister. Lord Dawson of Penn has recently drawn attention to the same matter in an admirable address on "Medicine and the Public Welfare," published in the *British Medical Journal* on May 9 last. It is a contribution which should be read and re-read by all who have the conservation of the national health and the welfare of the medical profession in their keeping. Lord Dawson refers to the disability which the existing State-aided hospitals in this country are under by reason of the fact that personal advancement of the medical staffs—in other words, a higher salary—can only be achieved by relinquishing clinical medicine for an administrative post. This is why many of the more active clinical minds, who see only the prospects of a dead-end in State-aided hospitals, have preferred, and still prefer, to link their fortunes to the gamble of an unpaid appointment on the honorary staff of a voluntary hospital.

Traditions of the Voluntary Hospital

The lure of the British voluntary hospital to-day is as great as ever it has been, thanks to its traditions, based largely upon the untrammelled conditions under which its staff work and the healthy criticism to which all are subjected. Its strength lies in these traditions and the proved service that it has been able to render to the community.

It is a great day for the young physician or surgeon when he is chosen from his fellows as being worthy of a position on its honorary staff. He may not have a "sou" in his pocket, and he probably knows that years of hard work lie in front of him. At the same time he has the satisfaction of joining an institution where the only criticism he is likely to receive is the friendly judgment of his colleagues and his students. He is answerable only to his patient and to his own conscience. Further, he knows that material prizes are within his grasp should he prove worthy of the trust laid upon him—prizes that, perhaps, are not measured in terms of finance, but which will be more satisfying than worldly wealth when the retiring age is reached and the time comes for him to hand over his charge to another.

The patient admitted within the walls of a British voluntary hospital knows also the human atmosphere, apart entirely from efficient medical service, that is a tradition of the institution He knows that he is not a mere cipher in the medical organization of the State. His case is the personal responsibility of a surgeon or physician, whose services are available to him at any time of day or night, should they be required. There is no question of official hours of duty, just as there is no "clocking in" and "clocking out" for those responsible for his welfare.

Difficult times undoubtedly lie ahead for the voluntary hospitals owing to the economic conditions which are likely to prevail at the conclusion of the present political world upheaval. These difficulties must be faced, but in planning for the future let us not cast aside as worthless those traditional principles which have placed the voluntary hospital in its present honoured position. Rather let us incorporate them in the State hospitals of the future. Part-time as opposed to whole-time service, with a corresponding reduction in fixed salaries, combined with freedom of action in professional matters, would remove many of the disabilities under which the medical officers of public assistance hospitals now work.

On the other hand, State aid may be necessary to supplement the income derived from contributory schemes in the case of existing voluntary hospitals. Donations and legacies are likely to become less and less as the State increases its demands upon the private purse for the development of social and other services. The provision of State aid, however, need not necessarily imply State domination. This important principle receives expression in Clause 72 of the Planning Commission's report, in which it is stated that the Regional Council or authority "would not interfere with the internal organization of individual hospitals." I trust that this very important observation will never be overlooked should the establishment of Regional Hospital Councils become an accomplished fact.

The Rising Generation in Medicine

During the short time that remains may I draw attention to a few matters which concern the rising generation in medicine? The medical student to-day is entering upon his career at a very difficult time, and I am profoundly sorry for him. The young people who one day will be shouldering our responsibilities are trying to assimilate the necessary facts and experience to satisfy the examination boards under conditions which are not conducive to the maintenance of our best traditions. Their interests are divided between professional and national duties. They are under an obligation to qualify in the shortest possible time, and they receive their education at the hands of a depleted staff whose members are often overworked and unable to give of their best. The profession has become purely utilitarian. At no time, therefore, is it more important to instil into the student mind those high principles which for so many years have guided the practice of medicine. There is, I fear, a growing tendency among students to-day to regard medicine purely from a materialistic standpoint. Even before the war many of the newly qualified, anxious to convert their acquired knowledge into terms of solid cash, rushed into contract or panel practice without holding any hospital house appointment whatsoever. Since the war the shortage of medical personnel has led to a greater demand for the newly qualified student, and the high fees now paid to temporary locums and assistants cannot but be harmful in the future when the period of present cheap money is past.

Another present-day aspect of medical student life which personally I much regret is the innovation of political student societies. It is a tradition of British Medicine, as it is of the British Red Cross, that our service is independent of political creed. The doctor should be entirely impervious to political influences. His concern is with the great essentials of birth, life, and death, which transcend all other considerations, and he should resolutely turn his back to the rival claims of political factions both at home and abroad.

Faults in Medical Education

In the present wave of optimistic post-war planning it was not to be expected that the perennial subject of medical training would escape the infection. It is well that this should be so, for it is obvious to most of us who are responsible for the teaching of clinical medicine that our present methods fall short of what is desirable, or in fact necessary, to equip the student for the world in which he will carry on his life's work after he leaves his "Alma Mater." The main object of our medical schools should surely be to produce the finest type of that traditional and honoured symbol of British medicine to which I have already referred—viz., the family practitioner. Are we doing that to-day? It appears to me that the whole system of our medical training requires revision, and therefore I welcome the fact that an Interdepartmental Committee on Medical Schools is already at work on this important matter. A major fault in our present medical education is the lack of cohesion between those responsible for welding the individual parts of the finished machine. Each teacher and each department, influenced no doubt by the advance of knowledge and anxious to communicate that knowledge to their students, overweight their subject with a mass of detail that can only harass the student mind and increase his anxiety as the examination time approaches. The pre-clinical teachers, endeavouring no doubt to establish a sound framework upon which modern clinical medicine can be built, try to crowd more and more into their lectures and classes. The surgeon makes his dressers stand long hours and witness tiring operations which the majority will never be called upon to perform. The clinical physician asks for the attention of his clerks while he discusses the intricate and highly scientific details of some knotty problem which most of his audience may never meet. The result of all this is that the average student finds himself qualified, and launched into a world which offers a strange contrast to the one where he has been educated. Shock No. 1 will be the revelation that concentrated scientific knowledge is not the only, or indeed most important, asset when in contact with his fellow-men and patients. He will find that he must be a human being first, and a doctor after. Shock No. 2 when he enters practice will be the discovery that he may not have available the necessary adjuncts for the application of all that he has learnt. There are other shocks in store for him, but let us hope that they will be fewer when the work of the Planning Commission reaches fruition.

To convert some of my criticism into practical politics, is it not possible for those responsible for the organization of medical training to envisage a more generalized and less comprehensive course of teaching than that now in being? Let there be in medicine a "School-leaving Certificate" at the end of, say, a five-years curriculum, as distinct from a "Higher School Certificate" awarded at the end of a further year's training devoted to some special aspect of medical work. Certificate A would not entitle the holder to the independent practice of his profession, but it would qualify him to become an assistant in family practice or in any of the special aspects of medicine which appeal to him. At the end of a further year's work he would secure Certificate B—i.e., the higher qualification—which would launch him upon his life's work. The concept of attaching a Certificate A student to a doctor engaged in the work of general practice appeals to me as a modern counterpart of the old apprenticeship system. The young man fresh from hospital would gain the experience he now lacks and learn to appreciate the fact that in life it is not so much what one does as how one does it. On the other hand, the older family practitioner would constantly be in touch with the vitalizing stimulus of the young and active scientific mind. Surely nothing but good could evolve from the liaison.

Prospects in Medical Practice

And, finally, what prospects have we to offer to the medical man or woman of the future? If the major proposals of the Planning Commission are accepted in principle and duly implemented I think we may safely say that many of the difficulties under which the profession now works will have been removed. The doctor of the future will have the satisfaction of doing good work with the increased facilities that are available to him; he will be better able to apply to his patients those methods of diagnosis and treatment which he was taught during his student years; and, finally, owing to the co-ordination of all the various health services, he will know that he forms an integral part of a great organization whose sole object is to maintain the health and happiness of the nation it serves.

My theme to some may have appeared retrogressive or irritating. I can only reassert my personal conviction that, whatever "new order" may arise in the conduct of medical practice, the future happiness of our people is intimately bound up with the maintenance of our British tradition in medicine that a patient is a patient and not an impersonal unit in a system.

MALINGERING

BY

RANKINE GOOD, M.B., Ch.B., D.P.M.

Captain, R.A.M.C., Graded Psychiatrist

The brief references to malingering (the conscious adoption and exploitation of symptoms of illness, physical or mental) in standard textbooks of medicine may be regarded as silent testimony to the rarity with which the condition is encountered in civil life. On the other hand, there may be lack of interest in the subject or difficulties in the clinical approach.

I have met with three civilian cases. The first was that of a vagrant to whom the prospect of a sound night's sleep with an assured breakfast to follow was sufficient motive: some months previously he had undergone a three-weeks investigation at the same hospital for his alleged gastric complaint and had been dismissed at the end of that time as a case of functional disorder: he hinted vaguely that identical investigations had been performed at other hospitals in the interval between his two admissions, with similar results. The second case was also that of a vagrant, similarly motivated, who trafficked on his habitual pallor and prematurely senile appearance to secure admission to hospital for investigation as a potential anaemic. In the third case the man, like the schizoid Hamlet, was resolved to "put an antic disposition on" in an endeavour to, in his case, escape from the pressing attention of the police for illegal misappropriation of money. These three were clearly abnormal people. Other cases are occasionally encountered (particularly in connexion with alleged injuries—of which no evidence shows—sustained in motor-car accidents) in which the diagnosis of malingering cannot be applied, solely through the lack of a confession to that effect from the "patient," whose desire for monetary gain overrides his truthfulness; these cases, of course, are altogether distinct from the genuine traumatic neuroses occurring in the same circumstances.

Wartime Cases

In wartime, perhaps because of the importance of morale and discipline, more frequent references to malingering appear in medical literature, although it is generally assumed that, so far as the war of 1914-18 was concerned, it was of rare occurrence (War Office Report, 1922a). Hurst (1940) lays down two criteria for the certain diagnosis of malingering—either detection *in flagrante delicto*, or an unforced confession from the man in accordance with the facts observed. The methods adopted by malingerers vary: a comprehensive account of these is given by Buinewitsch (1941).

In the examination of neurotic patients the physician often adopts a too confiding attitude, or, on the other hand, a too sceptical attitude which confounds the hysteric with the malingerer. In the hysteric, the production of conversion symptoms is motivated and effected without clear recognition by the patient of the processes involved. Similarly, while undoubtedly the hysteric in the Services does tend to exploit his symptoms more than he did in civil life (e.g., reporting sick with his complaint every day since conscription, whereas he attended his civilian medical practitioner once fortnightly or monthly), this exploitation is seldom recognized by the patient, however apparent the underlying motivation may be to the observer. It is well to bear this in mind; for, as a consideration of Case VI will show, malingering may be a mere incident during a schizophrenic episode occurring in a mental defective: further, the symptom produced by the malingering may be followed by the development of hysterical symptoms in the affected part. The explanations of malingering hitherto given disregard such things as the malingerer's choice of symptoms and the basic personality structure and attitude which allows him to malinger.

This communication may be regarded as a contribution to the solution of these problems. To this end, 6 cases will be quoted and points common to all of them discussed. Only the relevant details are given.

Case I (Psychopathic Personality)

At his entrance medical examination this man had turned up with the external auditory meati plugged with face-cream in an endeavour to feign deafness, and he had pretended idiocy when asked to read the Snellen test types. Actually his mental age was 12 5/12 years. An officer of his battery stated: "Sympathy and help did not have the desired effect of improving his work. . . . He became persistently worse . . . started the habit of grumbling and leaving fatigues when not under supervision . . . and has no desire to soldier." The M.O. stated that the patient was always reporting sick, made contradictory statements, was unappreciative of help, and would not co-operate. On admission to hospital the man was quite frank with me when I asked him if he was "swinging the lead." He informed me that he had a horror of bloodshed, and for that reason had by his malingering wished to avoid conscription four months previously. His previous history showed that he was an aggressive individual, had had marked phobias in infancy and childhood, and since leaving school, at which he was backward—most probably through inattention and an absence of any desire to learn—he had, between lengthy spells of unemployment, been in several jobs which he left because the work was "too hard" or "too monotonous." On one occasion he was sacked because he left his work "to go out and have a drink." He attributed all his troubles, past, present, and to come, to his wife, who he said had made a cuckold of him, and to his mother-in-law, who was a devil's dam. He spoke of them with an angry display of emotion which left him incoherent and speechless. He concluded by saying that life was not worth while in the circumstances, and that suicide as a way out was under contemplation. I agreed with him that suicide in his case would offer the best solution to his difficulties, and suggested simple methods whereby he might accomplish this effectively and undisturbed. Much taken aback, he rejected all I had said to him by stating that he had never given the subject a thought. As with his malingering, he was again shamming.

Case II (Psychopathic Personality)

This patient had been in two hospitals for 11 days before his transfer as a case of functional condition. He had had what was apparently a genuine fainting attack, after which he was admitted to hospital in a stuporous condition, with a pulse rate of, on one occasion, 48 a minute. When he came-to 4 days later there was a weakness of his left side. When I first saw him this weakness consisted of what I took to be a hysterical paralysis of his left hand, in no way differing from other similar paralyses I have seen—dusky blue, swollen, cold, and clammy. Circumstances precluded any treatment at the end of his first interview save the reassurance that I was satisfied from my examination that there was no structural disability which would account for the appearance and complete powerlessness of his hand. He had merely lost the idea of how to use it. It was up to him to accustom himself to the idea that his hand was perfectly normal and capable of use and that a decided improvement would be evident on the next occasion I saw him. Such improvement was, however, not forthcoming. I then attempted some very superficial interpretation from the point of view of motivation, reminding him of his statement, "I don't like the Army, and never will," made during t
previous interview, and how he might have had, unawares a
in the depths of his mind, developed the symptom of
paralysed hand as an excuse, as it were, for his discharge.
also pointed out to him how this method of being quit of
Army was probably suggested to him by a similar affection
had had seven years previously (of which he had previou
informed me), when, working as a tea-boy to builders,

he was never in any school fights, was bullied, and avoid
sports. He first came into contact with the civil police wh
he was 10 years old for stealing: for this he served 15 wee
in a reformatory. Since then he had been seven times charg
and convicted, chiefly for receiving, the last term of impriso
ment being for eight months. After serving this, he felt: "
I didn't join up" (one month before the outbreak of war) '
would be in Dartmoor before long." Since joining he had be
seven times charged with absence without leave.

When he first reported sick he presented what might ha
been taken for symptoms indicative of an anxiety neurosis.
was sceptical about the genuineness of his complaints, partic
larly since he was again awaiting trial for absence witho
leave. An unforced confession was ultimately obtained th
he was malingering with the object of escaping trial or obtai
ing a recommendation for mitigation of sentence on medic
grounds.

Case IV (Mental Defective)

Even before admission this man was suspect, his adm
sion notes stating that "the act may have been committ
to get away from the place." "The place" was a lonely sp
on a loch-side to which four corporals and he had been post
to open up a station. Fed up, he said, with the complete la
of social life, not helped by the four corporals keeping
themselves (from the facts available he did not appear to
paranoid about this), he walked into the loch in a feign
attempt at suicide in order to get away from the pla
Similarly, when shaving, he had made a great display of
razor. His mental age was 10 5/12 years.

Case V (Psychopathic Personality)

Admitted with a history of having given himself
after nine months' absence without leave and pleading lc
of memory for the lapse. He persistently maintained that
loss of memory was genuine or that it was at times parti
permitting him to get married and to wander around in
battle-dress (despite the fact that he had no ration cards) doi
odd jobs. His story was so grotesque that his statements we

accepted with some reserve. Ultimately he confessed that his story was fabricated. He had become "fed up and couldn't stick it" (the Army), purposely deserting to return to his civilian job on a trawler (on which, incidentally, he had made a voyage to Iceland), marrying during one of his spells on shore, and ultimately giving himself up on his wife's advice. His M.A. was 14 11/12 years.

Case VI (Schizophrenia)

Was admitted to a general hospital for eight weeks for treatment for an attack of gonorrhoea. During this period he had become depressed ("fed up") on account of all his articles being marked and his having to spin unconvincing stories to his fellow patients (by whom he said he was ultimately shunned) as to why he was so discriminated against. His attitude when he came out of hospital was: "If you're not good enough to mix with people you're not good enough to soldier with them." One week after his discharge from hospital his rifle, which he was hurrying to put away in order to get to tea, discharged accidentally, the bullet going through his left great toe. He himself had not loaded the rifle, nor did he understand how it came to be loaded. Expatiating on his attitude to the Army, he said, "I never did care for the Army," in which he was slow at "picking things up." His mental age was 8 7/12 years. Concerning his previous history, he said he had always been nervous and had phobias associated with darkness and loneliness, and if ever he found himself in such circumstances was afraid he might be attacked from behind. He also had phobias associated with water, heights, cows, and horses; he was a lifelong nail-biter, was shy, blushed easily, and said, "I kept myself to myself, more or less": he was a "mother's boy." Hysterical symptoms had supervened in connexion with the gunshot wound of his foot: there was a moderate degree of cyanosis and paralysis, due, he said, to pain associated with the healed wound which caused him to limp.

It was not until these hysterical symptoms were removed with treatment that he confessed to the previous existence of auditory hallucinations which made him think he "was going soft." His attitude towards the Army, the unbearable separation from his mother, and his auditory hallucinations all combined to make him thoroughly "browned off," in which state of mind (he now confessed) he shot himself through the great toe in an endeavour to be quit of the Army and to be returned to the home life in which the care and sympathy he needed would be forthcoming. (It should be noted that his hallucinations had no bearing on his deliberate conscious attempt to avoid service by shooting himself—e.g., the men's voices he heard holding everyday conversations did not tell him to shoot himself.)

Analysis of the Cases

From a study of these cases, of which only brief details have been given, certain aspects of malingering emerged conspicuously.

In the first place, the choice of symptom (i.e., insanity, paralysis, gunshot wound, or amnesia) was apparently largely determined by unrecognized emotional factors rather than by any intellectual process. In all cases save Case II no reason for the choice of symptom was given other than "It was all I could think of," "I don't know," etc. Case II, after stating that his "paralysed" hand might have been suggested by his previous accident, subsequently said that he doubted very much if that were the real reason. Since no analytical treatment of these cases was attempted it is perhaps unwise to speculate as to what the factors determining the choice of symptom were. Nevertheless, it was very noticeable that all cases (including Case I—only superficially aggressive) clearly showed a mental attitude in which a desire, a thirst for punishment, was dominant, though the patient himself was unappreciative of the existence of this desire. The point was well illustrated in Case III—his having been bullied at school because he was afraid to hit back, his repeated trouble with the police and subsequent punishment, and finally his attempt to escape from them by volunteering for an organization which has discipline and unquestioning obedience for its mainstays, an organization which, following a short period of service in 1927, had discharged him after he had served 56 days' detention for absence without leave. His phobias had also been used as vehicles for punishment—e.g., despite his dread of water he had worked for a spell on a tugboat until he fell into the water "by accident" (he was a non-swimmer); and, despite his dread of heights, he had worked for a spell as a riveter's mate until he fell "by accident" down the hold of a ship under construction. They also led him, after his discharge, to return to a city which has been repeatedly and heavily bombed, despite the fact that during a previous leave he had sustained slight physical injury during a "blitz" then in progress—a city in which his old temptations are awaiting him.

Closely associated with this desire for punishment, a marked attitude of infantile dependence was present in all cases, well illustrated in Case II, who had always sought and expected "pity and sympathy from other people," and in Case VI, whose desire to return to his mother amounted to a craving. This attitude was pronounced in Case I, who was desperate to get home to look after his mother although he was a married man with a wife and child. It is no digression from my theme (indeed, it is fundamental) to expand this point concerning the patients' attitude towards mothers whom absence has tended to idealize. Not infrequently, in actual fact, the mother has beaten and in other ways has psychologically misunderstood and mistreated the patient from his earliest days. This is of very frequent occurrence in psychoneurotics. The craving for "the good mother" is usually quite open and apparent in those of low mental age, and is concealed, disguised, and rationalized in more intelligent patients. The desire to be near the mother is remarkable in that while it is very real it is apparently unreasonable; for, on inquiry in all such cases that I have examined, it is found that the mother is quite capable of looking after herself and is suffering from no untoward domestic, pecuniary, or other distress.

Further inquiry elicits the fact that this desire on the part of the patient is not by any means of recent origin but has exerted itself with the same abnormal intensity and persistence as long as he can remember. As I have already said, it does not always show and has not always shown in an open longing for the good mother. It may show instead in a deep attachment to and affection for her house and home, etc., or to the wife, who frequently is an obvious mother-substitute. This attitude is natural up to a point, but in the cases under discussion it is quite pathological. It is no exaggeration to say that these patients are still psychologically united to their mother by an emotional "umbilical cord," the forceful severance of which produces the most intense anxiety, which he is constitutionally incapable of mastering adequately. In other words, however much the psychoneurotic conveys the impression that he is fully adult, he still remains emotionally immature. The terrified scream of an infant when faced with a danger that appears overwhelming may have as its adult variant the blind panic of a man who exposes himself to the fire of his own guns during an enemy bombardment: in moments of stress he tends to revert to a state of infantile helplessness, a terrified bewilderment—a state exerting the most pernicious influence on his fellow soldier, whereas it is expected of him that he will "acquire such a standard of morale as will enable him to put the welfare of his unit before his own personal safety" (War Office Report, 1922b).

The second aspect which emerged conspicuously from the study of these 6 cases was that all showed an entire absence of guilt-feeling in connexion with their malingering—entirely different, if such a thing could be imagined, from what would occur in a well-adjusted personality who resorted to such methods. Now, the absence of guilt-feeling in circumstances in which a normal person would experience it is the hall-mark of the psychopath. The term "psychopath" is used in this instance in the very narrow sense as defined by Henderson (1939)—briefly, the existence of a peculiar state of mind which does not render the patient certifiably insane, which causes him to exhibit conduct of an antisocial or asocial nature, and on which treatment or punishment has no deterrent effect. (The discrimination between the psychopath whose intelligence is average or above and the moral imbecile who is of low intelligence would seem to be purely arbitrary: fundamentally, the psychic attitudes and reactions towards their environment and its problems are the same in both cases.)

In the third place, all 6 cases showed a pronounced anxiety concerning military service, the extent of this anxiety being out of all proportion to the circumstances engendering it. Their malingering was, indeed, an endeavour to overcome this anxiety by the simple expedient of attempting to remove themselves, by the simulation of symptoms, from the circumstances which gave rise to the anxiety.

Disposal of the Malingerer

So far as the relation of the malingerer to the Army is concerned, it is essential to consider two points. The first of these is that the man's absence of guilt-feeling concerning his malingering leads to punishment or treatment having no deterrent effect on the future repetition of such conduct. The second point—and this is of the utmost importance in wartime—is the repercussion which the malingerer's conduct and mental attitude may have upon his Army comrades and, through them, upon military efficiency in general. It has already been pointed out that the malingerer is in a state of extreme emotional immaturity. Consequently, he has broken down in adult circumstances which were successfully withstood by his more strongly constituted brothers-in-arms. In these circumstances he reverts to a state of open childishness. He may grumble and grouse: his work, his adult capacity for work, falls off; he continually reports sick and is unappreciative of and does not co-operate in the treatment prescribed; he becomes a burden to all with whom he comes in contact in the environment for which he has a phobic anxiety; he develops the craving to return to his home, where the only real security he knows of is to be found and where his childish immaturity is understood and the pity and sympathy he has always expected from other people are forthcoming.

All this is clear and understandable, and in peacetime one could leisurely endeavour to wean such a case to a more adult independent state. When, however, he is a member of the fighting Services, and when the interests of the individual have of necessity to be subordinated to the group, this is out of the question. It is demanded of him that he "become a man" and "put away childish things"—which he is constitutionally incapable of doing. In his behaviour and attitude he is expected to contribute to the promotion and maintenance of good morale, instead of which he mopes about his group a potential and extremely dangerous menace to good morale in the more susceptible (i.e., the more emotionally immature) of his as yet mentally healthy comrades. Infectivity in these circumstances is as real a threat as the potential infectivity of a typhoid carrier in the physical sphere, as Wittkower *et al.* (1941) point out.

This constant and dangerous menace to good morale is, in effect, the crux of the matter concerning the disposal of the psychopath of this type in wartime. The report of the unit officers in referring the man to the R.M.O. when ordinary methods of producing correction have failed eloquently testifies to this. The paramount importance of the maintenance of excellent morale among soldiers has been appreciated from the earliest times, as also has its obvious remedy—namely, the ruthless weeding out of all influences adversely affecting morale. Such a view was arrived at by considered inquiry in 1922: "The occurrence of the [psychoneurotic] conditions militates against the efficiency of the Army, swells the sick returns, increases the amount of hospital accommodation and transport required, and absorbs the time and attention of the medical personnel" (War Office Report, 1922c).

The continued presence of these people in any unit thus tends to promote a vicious circle—infection by the psychoneurotic and the psychopath of the more mentally immature of previously mentally healthy subjects, with increase of further frank psychiatric cases and a further lowering of morale. And the morale of an army is a barometer by which the fighting efficiency of that army can be read at a glance.

The removal of a weak link in an otherwise strong chain designed purposely to bear an enormous stress therefore requires no apology. Nor is it, as some might imagine, from a hasty assessment of facts, an admission of culpable failure. The psychiatrist, like the surgeon, can radically treat only those growths that are not beyond the reach of his therapeutic knife. In such cases, however, the psychiatrist is potent, from the prophylactic point of view, in removing a dangerous source of infection. Thereby he contributes not inconsiderably to the promotion of that morale and efficiency in the absence of which a fight is never won.

Summary

The malingerer is a psychopath with, among other features, a complete absence of guilt-feeling concerning his malingering. Although he consciously assumes and exploits symptoms of physical or mental illness, the variety of symptom adopted (i.e., whether amnesia, gunshot wound, insanity, or paralysis) is, however, apparently determined by an unrecognized masochistic and very infantile dependent attitude.

Malingering is a defence mechanism employed by a constitutionally weak ego against a real but unreasonable and intense anxiety concerning military service.

The disposal of the malingerer in wartime should be pre-eminently determined by considerations of military morale and efficiency.

I am indebted to Lieut.-Col. R. J. Rosie, R.A.M.C., for encouragement and permission to pursue these investigations, and to Major J. P. McGuinness, R.A.M.C., for his assistance in Case III and the details concerning his Case V. To both, and to Major T. F. Rodger, R.A.M.C., I am beholden for their constructive criticism of the script of this paper.

FOREIGN BODIES IN THE ALIMENTARY TRACT

BY

G. O. CHAMBERS, F.R.C.S.
Visiting Surgeon to H.M. Prisons

When Nature has provided so many problems in surgery to occupy scientific attention it seems inconsiderate that man should, by accident or otherwise, go one further by self-mutilation in the swallowing of foreign bodies. These cases, however, tend to provide compensations in the element of surprise and the interest they arouse, and create an atmosphere akin to the treasure hunt until such time as the quarry has been unearthed or retrieved. The excitement of all this inclines to be somewhat tempered by the fact that the majority of these perverse individuals are of dubious use to society and, moreover, in some cases develop a morbid appetite for foreign bodies. For some strange reason they seem to stand abdominal section well and develop peritoneal antibodies that serve them to such good purpose that either septic complications are avoided or their relative dangers are overcome.

This paper refers chiefly to intentional swallowing and not to cases of accident occurring usually in children and normal adults, with whom small articles swallowed—inadvertently—have a safe passage. The open safety-pin, fish-bone, or needle may cause trouble by impaction or perforation and necessitate removal. The cases under review are those of adults in detention, in whom the swallowing of large, irregular, and ill-assorted articles is the main feature. Only 3 cases are reported as accidental, and concern the loss of two needles and a small denture.

Psychology of the Intentional Swallower

The psychological aspect of the intentional swallower is interesting, and varies in type with the environment and mode of life. In all there is an underlying psychological framework of egoism, vanity, and self-attention.

From time immemorial this faculty has been utilized as a means of livelihood in exhibitions such as the swallowing of a sword, watch, or live goldfish—duly returned unharmed from their immersion in the stomach. Proof of the last-named performance was given a few years ago at a medical society in London, where an astute radiologist inserted some small lead shot inside each fish—through its mouth—so that their movements in the performer's stomach could be observed with the radiological screen. The possessor of a pharyngeal pouch sometimes uses it as a financial asset for the disappearing-watch trick. An *x*-ray demonstration on a performer of this act at the above meeting was declined, as no doubt he wished it to remain a mystery.

Under conditions of restraint the psychological factor becomes intensified and certain prisoners take up an attitude stubborn, defiant, and antisocial to their surroundings. The mental picture is best described by Dr. W. Norwood East in his interesting book, *Medical Aspects of Crime* (1936), in which he says: "A few of these prisoners are insane, but the majority are not. Most of them are ignorant of the dangers they incur, and are reckless of injury in their attempt to defy authority or exchange imprisonment for the comforts of a civil hospital. . . . Many offenders who swallow foreign bodies are psychopathic personalities. Vanity prompts others to attempt to secure the admiration of their fellows by these means. . . . The unconcern with which an hysteric regards a mass of foreign bodies, including dinner forks and pieces of sharp metal, in his intestinal tract is very striking."

In a few instances an element of concern in not wishing to cause too much bodily harm to himself is evidenced by previous removal of the prongs of a fork or the ladle end of a spoon. These individuals are usually hysteric delinquents. One patient swallowed some cotton-wool before taking 9 foreign bodies, presumably with the object of lessening the risk of impaction or perforation.

Treatment

Where the condition is quiescent, palliative measures are given for a reasonable length of time. These consist simply of a dietary such as porridge, bread, pease-brose, vegetables, and perhaps chopped-up string. Periodic *x*-ray examination is carried out; and, in the case of operative measures, as near as possible before operation. Careful examination of all stools and vomit should of course be made. Small articles may ultimately be assisted from the rectum by enema, by digital aid, or through the proctoscope. In general, 6 weeks may be taken as a rough guide to the period a foreign body which is producing no symptoms may be left *in situ*. Finally, in suitable cases—chiefly accidental—the patient's fears should be allayed by the reassuring attitude of the medical attendant.

The Table shows a series of 16 cases that were sent to hospital for surgical treatment between 1936 and 1939. Cases considered not urgent were observed for a variable period and checked up by *x*-ray examination. The minimum time a large foreign body remained in the stomach before extraction was 6 days. In urgent cases requiring operation reliance had to be placed on the history and clinical signs, with or without previous *x*-ray examination.

Points of Interest

From these sixteen cases it may be of interest to note that:

(*a*) Eight were found perforated, as follows: duodenum, 1 (Case 1); jejunum, 1 (Case 3); lower ileum, 1 (Case 12); caecum, 1 (Case 6); transverse colon, 2 (Cases 2, 8); pelvic colon, 1 (Case 5); right inguinal canal (? caecum or ileum), 1 (Case 7).

(*b*) All these perforations were in situations distal to the pylorus, 4 of them distal to the ileo-caecal valve.

(*c*) The case incidence of perforation in this series was 50%, and all beyond the pylorus. This indicates that the patient is not necessarily out of danger when a foreign body has managed to pass the pylorus.

(*d*) With the exception of Cases 6, 7, and 8 the cases of perforation presented signs of acute abdomen with sudden and intense onset.

(*e*) Case incidence of impaction with intestinal obstruction was *nil*.

(*f*) Case incidence of impaction in the second part of the duodenum or at the ileo-caecal valve was *nil*.

(*g*) In no case did an ordinary intact fork or dessert-spoon, average length 7 in., or other article more than 1 in. in width, pass through the pylorus (Cases 4, 11, 13, 14, 15, 16).

(*h*) The widest article that passed through the pylorus was 1 in. (Case 2)—a piece of tin.

(*i*) The longest articles that traversed the duodenum were 5¼ in. and 5 in. (Cases 8, 12)—broken dessert-spoons.

(*j*) The widest article that passed the ileo-caecal valve was 1 in. (Case 2) and the longest 5¼ in. (Case 8).

(*k*) In one case in which a similar operation—gastrotomy—had been performed 7 weeks previously no evidence of the former wound on the stomach wall was visible (Case 15).

(*l*) Case mortality: 15 recovered, 1 died (6.25%).

Although the series of cases is a limited one and the type of foreign body rather different from and larger than that found in accidental cases, it is submitted that some findings at operation appear to run counter to certain of the views expressed in well-known textbooks on surgery and therefore may be considered unusual in this respect.

Choyce's *System of Surgery* (1932) states that: "The great majority of foreign bodies, having successfully passed the pylorus, safely traverse the remaining segments of the alimentary canal. The most common site of arrest is the lower part of the ileum, ileo-caecal valve, or caecum." Romanis and Mitchiner (*Surgery*, 1941) say that "foreign bodies are not commonly met with in the intestine as, if they pass through the pylorus, they will probably traverse the whole intestinal length and emerge at the anus. Elongated or heavy bodies will become impacted occasionally in the second part of the duodenum, and the only other point at which impaction is likely to occur is the neighbourhood of the ileo-caecal valve."

Maingot points out in his *Post-graduate Surgery*: "Very rarely does a foreign body, swallowed accidentally or intentionally, become lodged in the intestine. If perforation occurs the process is usually slow, resulting in either a localized abscess or an internal or external fistula." Rose and Carless's *Manual of Surgery* (16th edition, revised by Wakeley and Hunter, 1940) states: "Foreign bodies accidentally or intentionally swallowed occasionally pass through the stomach and become lodged in the intestinal canal. Lunatics and children are most frequently affected, and in the former the most astonishing collections are occasionally found. The symptoms caused by such conditions will be either those of intestinal obstruction or perforation. In the latter the process is usually gradual, rather than sudden, giving time for adhesions to form, thereby limiting the mischief. Suppuration follows, and possibly the foreign body may be extruded naturally or removed by the surgeon through the abscess cavity. Fragments of glass or metal may sometimes lodge in the pouches of the colon."

In the series under review the majority of the articles that had passed the pylorus and ileo-caecal valve were retained in the large bowel with signs of impaction or perforation. The sacculations, pouches, flexures, and sluggish peristalsis of the large intestine doubtless facilitate lodgment and, in some cases, perforation.

Commentary

Commenting briefly on certain cases, it may be mentioned that in Case 10 a small single tooth denture was searched for—on account of the haematemesis—but without success. This body may have eluded discovery by lodging in a duodenal pouch or diverticulum. The main point was its departure from the stomach and the subsequent freedom from symptoms. In Case 7 the supposition was a quiescent perforation by the needle through the caecum or lower ileum into the internal inguinal ring. This patient had undergone two abdominal sections previously and admitted to three separate occasions of foreign-body swallowing—a statement which was borne out by *x*-ray examination in each case. No. 12 was the only patient certified insane. He had no previous foreign-body history. In Case 9 operation was considered urgent, and was carried out the same night upon the history and failure of oesophagoscopy elsewhere. The transgastric approach was made. The location and extraction of the lower end of the foreign body (an impacted dessert-spoon) were difficult. Owing to the depth and curve, and to the failure of all ordinary forceps—curved or angular—to reach it, recourse was had to Cheatle's sterilizing forceps, which proved successful.

Recovery took place in all patients but one (Case 8), who died 24 hours after operation. He had a history of 3 former laparotomies for foreign bodies. The post-mortem findings showed small haemorrhages in the intestinal tract, atheroma, and myocardial degeneration.

Conclusion

It might be worth while recording a somewhat baffling case of trauma from a foreign body inserted into the lower orifice of the alimentary tract. There was a history of about 6 months' intermittent bleeding per anum whilst at another institution. There the patient was investigated on many occasions. Piles were suspected, and were injected. As bleeding continued he was removed to a hospital, where sigmoidoscopy and barium *x*-ray examination were carried out. Finally the patient consented to an abdominal exploration, which also gave a negative result. He was, however, much improved, and for a time there was no bleeding; later it recurred after leaving hospital. On admission to the surgical unit he appeared anaemic and wasted, with much loss of strength. His colour index was 0.9 and the red cells 3,500,000 per c.mm. Bleeding per rectum was present, mixed with faeces; wash-outs contained blood and occasional clots. Examination by proctoscope showed a deeply injected and

Table showing Details of Cases

Case No.	Description of Foreign Bodies	When taken	Past F.B. History	Condition on Admission	Findings at Operation		Result
					Peritonitis	Location	
1	Two 2½" needles, bits of glass, copper wire (the two latter passed before operation)	8 weeks before	Nil	Nausea. Slight epigastric pain and right rectus rigidity	Present; localized	(1) Needle in pyloric antrum of stomach—impacted (2) Needle in first part of duodenum—perforated	Recovered
2	Piece of tin (3" × 1"), penholder (4½"), pocket-knife (3"), toothbrush handle (4½"), small wooden spoon, 4 nails. (Maximum width of F.B.s other than the first was ¾")	2 and 8 days before	Laparotomy for F.B. in stomach 2 years ago	Acute abdomen; very ill	Present; central	(1) Piece of tin in transverse colon—perforated (2) Other articles—except nails—found lying free in pelvic colon (3) Nails felt free in rectum and left—passed 4 days later	"
3	Three large needles (triangular, pointed, 3"), one 2" needle, 2 bits of wire, 1 piece of tin, 1 piece of wood, 1 slate-pencil. (Maximum width of F.B.s ¾"; length 4")	14 days before	Nil	Acute abdomen; very ill	Present; gas and free fluid in pelvis	(1) One needle found free in peritoneal cavity—perforated through jejunum (2) Other needles, wire, tin, and wood found lying free in stomach (3) Slate-pencil free in jejunum (4) Doughy mass felt in ileum—? wool; left alone	"
4	Table fork (less prongs), length 5½", width ⅞"	6 days before	Two former abdominal operations for F.B.s	Nausea. Slight pain and tenderness over left epigastrium	No	Broken end of fork near greater curvature of stomach—impacted; other end in pyloric antrum—impacted	"
5	One 3" needle	7 days before. Stated by accident	19 days before (Same patient as Case 3)	Acute abdomen	Present; localized to lower abdomen	Needle found in pelvic colon with point perforating through wall. Ileus present. Many adhesions from former peritonitis	"
6	One 3" needle	3 weeks before. Accident	Nil	Tender in right iliac fossa over McBurney's point	No	Needle found perforating wall of caecum at a point ½" below appendix. Omentum wrapped round protruding needle. Surrounding area of caecum and appendix acutely inflamed	"
7	One 2½" needle	Unknown	Same patient as Cases 3 and 5 (five mths. later)	Pain and tenderness over right inguinal region; small lump, no impulse	—	Needle removed from right inguinal canal near internal ring. Much fibrous tissue present. No evidence of hernia or recent bowel perforation	"
8	One dessert-spoon (handle and shaft only), length 5½", width ¾"	10 days before	Three former abdominal operations for F.B.s	Acute abdomen	No	Spoon found in transverse colon impacted and on point of perforating. Many adhesions present	Died 24 hours later
9	One dessert-spoon, length 7", width of spoon 1½"; one 2½" needle	4 days before	Two former abdominal operations for F.B.s	Dysphagia. Presternal pain. Frequent retching. Inanition debility. Attempted removal by means of oesophagoscope at another hospital 2 days ago, but failed	—	(1) Spoon impacted in oesophagus. Tip of handle located 3½" above cardiac orifice by transgastric section. Impaction of ladle end of spoon near level of tracheal bifurcation. Difficult extraction by use of Cheatle's long sterilizer forceps (2) Needle removed from transverse colon	Recovered
10	One small denture—single incisor with metal clip, ½" × ⅜"	8 days before. Accident	Nil	Two attacks of haematemesis. Pain and vomiting. *X*-rayed on two occasions; second on day of operation	No	Stomach carefully examined by palpation externally, also whole of small intestine, lesser sac, and transverse colon—five times. F.B. could not be detected. Convalescence uneventful	"
11	One dessert-spoon (minus handle), length 6", width of spoon end 1½"	4 weeks before	"	Epigastric pain. Nausea. *X*-ray report: "in transverse colon"	"	Spoon found in stomach with broken end of shaft impacted at greater curvature	"
12	Handle and shaft of spoon, length 5", width of handle ¾"; one safety-pin (open)	Unknown. Insane	"	Acute abdomen	Present; localized	Spoon handle and safety-pin found in lower ileum, which was perforated in two places. Intestinal contents had escaped into pelvic cavity	"
13	One fork, length 6⅞", width ¾"	10 days before	"	Nausea. Epigastric pain. Right rectus rigidity	No	Fork found in stomach—impacted between greater and lesser curvatures	"
14	One fork—size as Case 13	7 days before	"	Nausea. Retching. Epigastric pain	"	Fork found lying free in stomach; handle towards pyloric antrum	"
15	One fork—size as Case 13	Unknown	Laparotomy for F.B. 7 weeks before (Same patient as Case 14)	Symptoms as above	"	Fork found free in stomach—handle presenting. Scar of former gastrotomy not visible	"
16	One fork (size as Case 13), 3 steel rings, 1½" diameter	6 days before	Nil	Nausea. Occasional vomiting. Epigastric pain	"	Fork found free in stomach, also rings, although the latter were somewhat elusive	"

velvety appearance of the anal mucosa and lower third of the rectum. Above this area the surface was normal. Some form of self-infliction was suspected, and close observation was kept for several weeks without result. All this time the patient was kept in bed on a milk diet. It might be mentioned that he was most co-operative in treatment, grateful for all that was being done, and often expressed a profound wish to get better. He was alert, intelligent, and an ardent book reader. At length the mystery was solved. While the patient was in the theatre for a final proctoscopy an intensive search, one of many, was being made of his bed and belongings. Concealed in the binding of a library book were found two pieces of twisted wire, 2 to 3 inches in length, with the ends set apart at one extremity—designed to create trauma and haemorrhage. The wire had a faecal odour. Confirmatory examination by microscope and spectroscope revealed blood cells, *B. coli*, and a haemoglobin absorption band. From this moment the patient rapidly got well.

I should like to express my thanks to the Commissioners, H.M. Prison Commission, Home Office, for permission to publish this paper, though it does not necessarily represent their views.

PERIODIC MEDICAL EXAMINATION

BY

FRANK ELLIS, M.B., M.Sc., F.F.R., D.M.R.

Since periodic medical examination was suggested by Dobell (1861) it has made little or no headway. This may be due to medical apathy, since it is easier to work as individuals in medicine, but almost impossible to carry out such examinations without organization. On the other hand, it may be due to the fact that considered medical opinion disapproves of the principle, regards the procedure as scientifically unsound, ineffective, or impracticable, or regards the necessary administration and organization as too difficult under conditions hitherto existing in medicine and its relation to society. There is such attraction, however, in the idea that by periodic examinations minor tendencies to major maladies can be detected and thus corrected relatively easily before breakdown of the organism occurs that I think the evidence on the question should be reviewed, and the possibilities of the applicability and value of such examination assessed.

The great fault of the present method of bringing the doctor to the patient is that in most cases the doctor is not called at the beginning of ill-health, but when the compensation which is characteristic of the vital organism is failing the individual in his attempt to live up to his usual standard of efficiency. Periodic examinations, if they offered an opportunity for detection and correction before this failure of compensation occurred, would constitute an important branch of the preventive medicine which is rightly emphasized in the Medical Planning Commission's interim report (1942) as one of the most important functions of the medical practitioner.

Studies from the Literature

Sir James Mackenzie was able to make his contribution to modern cardiology as a result of carrying out regular examinations, and he emphasized the necessity for a systematic study of the beginnings of disease. Apart from the work of his disciples at St. Andrews, however, nothing on the subject has been reported in this country except from the Peckham Health Centre (1938). In America, following recommendation of the procedure by Dr. Gould in 1905, various sporadic individual attempts have been made to carry out such examinations, the most noteworthy being those of the Life Extension Institute, an account of which is given by Fisk (1923) and Fisk and Crawford (1927). Like the Peckham group, they report a high incidence of unsuspected defects in the apparently healthy. They assess the ratio of major to minor maladies as 1:10, and stress the fact that considerable relief follows the correction of minor complaints. Other published work is mostly American, and the relatively high incidence of defects in apparently healthy individuals is supported by Page (1938), Faught (1939), Ryan (1927), Griswold (1940), Brandabur (1937, 1940), Harrison (1938), and Emerson and Irving (1938). From the Continent comes similar evidence (Kattentidt, 1933).

Assuming that such defects can be found, it is important to know if they can be corrected. The Peckham report says the course of many maladies has been arrested with success and with satisfaction to the sufferer. Improvement in various conditions on subsequent examination is reported by the workers mentioned above, correction of from 50 to 70% of defects of all kinds being recorded. Noteworthy among these are reports of improvement and disappearance of hypertension following hygienic measures only (adjusted habits of life, etc.) by Brandabur and by Emerson and Irving. The former reports a recovery to normal in 114 out of 382 railway workers, and the latter report an average reduction in blood pressure of 18 mm. of mercury in 78 out of 120 sufferers found in 1,020 examinees. When it is remembered that the actuarial assessment of actual to expected deaths of men aged 40 to 49 is improved from 138 to 97% as a result of 10 mm. difference in blood pressure, the importance of these results can be appreciated (Actuarial Society of America, 1939).

Improved Expectation of Life

This appreciation based on ordinary life insurance examinations nullifies possible criticisms of the significance of these blood-pressure estimates. Caution because of possible inaccuracies in ordinary estimates is necessary, as emphasized by Bethea and Hardy (1932). The thoroughness of the periodic examinations determines the number and the nature of the defects recorded, but Mishler (1939) reports on the employees of a "Truck Line" system, 40% of whom were found to have defects on examination by general practitioners distributed over a wide area, while the Life Extension Institute (Fisk, 1923) found some defect in all of 10,800 males of an average age of 34 from typical industrial groups. That improvement in expectation of life results from such examinations is shown by a report of the Metropolitan Life Insurance Company of New York (Fisk, 1923). It is stated that instead of a mortality rate for seriously impaired life of 2½ times the tabular rate, it was only 82% of the tabular rate, and 38,000 lives were saved for the company in 1920.

In spite of the value of the procedure as indicated by these published findings, and although the American Medical Association publicly endorsed the principle of periodic medical examinations in 1922, the apparent popularization of such examinations in the United States is only relative. This is shown by Collins (1934), senior statistician to the United States Public Health Service, who, in a survey of a cross-section of 8,758 families, found that only 3% of the population at the age of 60 underwent periodic examinations, and that this was the maximum proportion after the age of 20. Thus it would seem that unorganized voluntary examinations only touch on the problem, and that a national effort is needed to make examinations an important part of preventive medicine. Organized examinations have been reported from France, Germany, Turkey (Asim Arar, 1938), and Russia (Fredlyand, 1938), while in Canada, Harrison (1938) states, "recent Canadian Provincial Health Insurance Acts make provision for periodic health examination."

It is my contention that all this evidence calls for the serious consideration of periodic medical examination on a national scale as part of our post-war medical organization. In addition to the immediate benefit to the individual which can reasonably be expected, it is anticipated that with adequate statistical analysis of thea findings carried out at central bureaux the significance of hitherto unappreciated facts in clinical history and examination will be assessed, with the result that early diagnosis of disease will be facilitated, and the emphasis in medicine will be on the physiological rather than, as at present, on the pathological. Such a scheme is not beyond the bounds of practicability. The cost should be a national concern, and it must not be forgotten that the saving of life and health would, taking the long view, probably more than pay for it. Fisk shows that for 105,000,000 people in America the gain, after deducting the cost of examinations and treatment, represented about $1,500,000,000; a proportional figure for the United Kingdom would be £100,000,000 a year.

A Suggested National Scheme

Any such scheme should be run by the general practitioners. In Detroit the school medical service sent school children to their family doctors for periodic examinations, 37,348 being sent in 3 years, and Shurley (1937) reports that it is intended to make this a routine procedure. The examinations should be routine, and preferably more than one doctor should be present, so that each acts as a check on the other to ensure that the work is well done. A consultant should be readily available. Practitioners should be adequately paid for their services, and nurses and clerical staff should relieve them of routine duties. They should be able to work in groups and at suitably arranged health centres, and postgraduate study should be insisted upon. The health centre should provide routine laboratory and *x*-ray facilities with specialist assistance for interpreting radiographs. The emphasis should be on abundant vitality as the normal state, and the general practitioner should be in a position also to observe the usual mode of life of the individual; as the Peckham group express it—his reaction to his environment.

The treatment of the sick (private and panel practice) should be carried out at the same centre, which might well be a part of the community centre of an estate, closely associated with its recreational facilities. Adequate records should be kept and duplicates sent to a central statistical bureau, which would be able to provide morbidity statistics, and, by correlating early symptoms with later events, facilitate early diagnosis. This advance in medicine is especially desirable in connexion, for instance, with cancer of the stomach. It may be that conditions such as Paget's disease and the aetiology of juvenile spondylitis might become better understood.

The national identity cards would provide a suitable basis for classification and making contact with individuals. It would be necessary to see that future generations of practitioners were taught the routine and value of periodic examinations. The public should be induced to come voluntarily, and taught through the Press, the wireless, and lectures to realize the importance to their children, themselves, and the nation of such examination. It is suggested that the present civil defence services, the Home Guard, first-aid parties, and schools and universities offer a method of rapid and wide diffusion of such instruction. The frequency of the examinations would be dictated at first by the limits of practicability, but even an examination every 3 years has been shown to be of considerable value. Irregular spacing might be found with experience to be best. It is considered, for instance, that during the first year of life (Peterman, 1937) very frequent examinations are desirable, and between the ages of 5 and 15 fewer may be necessary than later.

As a safeguard against the breakdown of a national scheme through practical difficulties, experiments could be conducted in which medical, administrative, and financial experience could be gained. Two types suggest themselves: (1) An experiment on an estate of about 5,000 people. This would be relatively inexpensive and capable of control because of the ease of contact between doctors and the public. It would provide useful information of the detailed working of individual health units. It could precede (2) an experiment for a large city. This would require a considerable organization, and mistakes might be relatively costly unless the preliminary experiment had been carried out. It would provide enough information to run a national scheme perfectly, but would have to be conducted by the Ministry of Health, probably through the local authority.

That the idea of periodic examination has an appeal even without knowledge of all the foregoing evidence is shown by the fact that a group of doctors on an estate in Sheffield are eager to carry out the first experiment. The success of the school medical service, with its necessarily rather perfunctory examinations, in improving the health of school children in this country is an argument for periodic examinations. With such a scheme should go some form of adequate social insurance as recommended in the Medical Planning Commission's report. The possibility of neuroses being caused by such examinations may influence the opinion of practitioners. Faught (1939), Sensenich (1938), Fisk and Crawford (1927), and Pokorny (1940) state specifically, however, as a result of experience, that neurotics are fewer rather than increased in number. It seems reasonable to suppose that children, if examined at regular intervals, would grow up as unconcerned at the prospect of a medical examination as they are of the dentist's chair, occupied at regular intervals.

Medical Memoranda

Congenital Diverticulum of the Common Bile Duct

This condition, sometimes called cystic dilatation of the common bile duct, is so rare (less than 100 cases have been reported) that any case of it is worthy of record. The pathology, aetiology, and variations in symptomatology, as well as the literature, have been fully considered by Sir James Walton (*Brit. J. Surg.*, 1939, **27**, 295).

CASE REPORT

The patient was a married woman aged 39. In her medical history there was nothing to suggest disease of the gall-bladder or bile ducts. She had, in fact, been remarkably free from illness of any kind. It should be noted that her first pregnancy terminated in Caesarean section three months before her admission to hospital. Ten days before admission she developed a severe colicky pain in the right hypochondrium, radiating through to the back and up to the right shoulder. On account of this pain she was admitted to hospital under the care of Mr. J. E. Paterson.

Examination revealed tenderness and guarding over the gall-bladder region. The liver edge could not be felt, and there was no palpable swelling. She was not, and never had been, jaundiced. Vomiting did not occur. There was no rise of temperature. A diagnosis of gall-stone colic was made, and an *x*-ray examination carried out. "Straight" *x*-ray films gave negative results, and cholecystography showed no evidence of gall-bladder shadow. The clinical diagnosis was considered to be substantiated and operation was advised.

At operation the gall-bladder was found to be healthy in appearance and of normal size. The first and second parts of the duodenum were lifted forwards and pushed down to the left by a large cystic swelling. This swelling, covered by peritoneum, was somewhat pear-shaped. The upper narrow portion extended up to the portal fissure lying in the gastro-hepatic omentum. About 1½ in. above the duodenum the cyst became more globular and measured some 4 in. in diameter. It extended down behind the first and second parts of the duodenum almost to the ampulla of Vater. The right border was definite and rounded, and extended beyond the limits of the duodenum. The left border was indefinite. Aspiration through a fine needle proved that the cyst contained pale-green bile in which there was a fair amount of mucus. There was no gross sepsis of the contents. The cyst was gradually decompressed by aspiration, but even when empty it did not collapse completely owing to the fibrous nature of its walls. No obvious obstruction to the duct was found.

A two-layer anastomosis between the cyst and the second part of the duodenum was made and the suture line reinforced with an omental graft. A drain was inserted into Morison's pouch. Leakage did not occur, and the patient made an uneventful recovery. When seen ten weeks after operation the woman was very well and had returned to work.

Since this note was written the patient has been seen again. Several times she has had attacks of pain in the right hypochondrium, and on one occasion has had a feeling of chilliness with slight shivering—symptoms which may reasonably be attributed to a mild infection of the bile ducts. The attacks were not severe or prolonged, but they deserve mention, as other reports give conflicting accounts of the incidence and severity of this complication.

My thanks for permission to publish this case report are due to Mr. J. E. Paterson, who performed the operation, and to the late Dr. W. Martin, superintendent of Stobhill Hospital.

Senior Resident Surgical Officer,
Stobhill Hospital, Glasgow.

Tenosynovitis in Untrained Farm-workers

The occurrence of a large number of cases of tenosynovitis crepitans among workers from this camp appears to be worth recording. Within a few months we have seen 16 such cases, 12 in men going out on farm work. As the average number of men doing such work at that time was 52 this forms a rather high proportion. The other 4 cases occurred in men doing some unaccustomed type of work in the camp. Of these 16 men 14 did office work or other non-manual labour in normal life, although no manual labour had been done by any of the men for at least 4 months. The tendons involved were the same in all cases: the extensor carpi radialis longus and the extensor digitorum communis—usually both, and in a few cases the latter only. These tendons are known to be frequently affected. Signs and symptoms were typical: swelling and tenderness along the tendon, with pain and crepitation on movement.

Treatment

Most of the men presented themselves at the camp hospital immediately upon the appearance of symptoms. Treatment consisted of rest, immobilization of the wrist by strapping, fomentation for two or three days, followed by radiant heat or infra-red treatment and massage with ung. iod. denigres. Under such treatment most patients improved rapidly and appeared to be completely cured within 8 to 10 days. Two cases which did not come under observation until almost 10 days after the onset took a much longer course and were not cured until 3 weeks after the beginning of treatment. In one of these cases immobilization by splinting had to be resorted to, since the patient would not obey instructions to refrain from using his hands. Two other patients, who interrupted their treatment prematurely and against advice, were forced to return by a recurrence of the symptoms, and thus the period of inactivity was considerably lengthened. In a further 2 cases some thickening of the tendon remained and is still noticeable, without, however, causing any pain or incapacity for work. Of the 12 farm-workers 11 returned to work of the same type immediately after the condition had cleared up: 10 were able to do such work without either inconvenience or recurrence of the tenosynovitis, but one had to give up on account of a relapse.

From our observation it would appear that treatment and rest should be started immediately upon the first appearance of the symptoms, thereby shortening the course and limiting the loss of working time, whereas neglect would tend to prolong the incapacity. The easy accessibility to medical aid in this camp and the necessity for reporting all ailments immediately may have made early treatment and diagnosis possible, whereas, normally, people outside might tend to disregard the first symptoms.

Causative Condition

All the cases seem to have occurred after work involving repetition of stereotyped movements, and it is our impression that inexperience in such work resulted in an incorrect and uneconomic muscular effort—a fault which was rectified by continued practice. It would be interesting to know of any similar accumulation of cases of tenosynovitis now that a large part of the population has taken up unaccustomed manual labour.

It is said that a rheumatic factor may be partly responsible for tenosynovitis. We certainly have seen a proportionately large number of cases of other rheumatic manifestations, such as fibrositis, in this camp, very likely due to damp houses and damp bedding, both of which are probably unavoidable under the climatic conditions. The question of a maladjusted nutrition (lack of vitamins, "too much starch," here usually made responsible for any indisposition) can probably be disregarded, as the farm-workers have their food on the farm and are the best-nourished section of the camp.

It seems remarkable to us that no cases of tenosynovitis have occurred among those who take part in sport, as the vast majority do, including men who for years have not played any games at all.

Synergic Action of Intravenous Mercurials and Gum-saline in Nephrotic Nephritis

Case History

The patient, a stonemason aged 42, was admitted to the Royal Halifax Infirmary on June 29, 1940. He had had malaria in 1917, and "winter bronchitis" for 20 years. He gave a history of 8 weeks' malaise and 6 weeks' puffiness of face and swelling of hands and legs. He complained of aching in loins, nocturnal frequency, occasional headache, anorexia, and nausea.

Examination showed pallor and wasting, with marked generalized oedema of the lower extremities, genitalia, and sacral pad; ascites with shifting dullness; and physical signs of basal congestion of both lungs. B.P. 160/100. Urine: S.G. 1028, acid; albumin + +; abundant hyaline, granular, and epithelial casts; no red cells. Blood urea: 26 mg. N per 100 c.cm. Blood: R.B.C. 4,500,000, W.B.C. 8,400, Hb 75%. Faeces: fluid but non-pathological.

Treatment with the following diuretic measures was attempted without success over a period of 3 months, the average urinary output remaining about 40 oz. in 48 hours: restricted fluid intake, high protein–salt-free diet, calcium lactate, thyroid, urea, aminophyllin I.V. 10 c.cm., and 12 I.V. injections of various mercurials (1 to 2 c.cm. novurit, mersalyl, and neptal), preceded by courses of ammonium chloride. An intraperitoneal injection of 4 c.cm. of neptal on Sept. 1 was followed by an excretion of 110 oz. of urine in 48 hours. Intravenous injection of gum-saline (6% gum acacia) was then tried (Landis, 1937). A drip infusion of 1,000 c.cm. of gum-saline was given on Oct. 14 without result. Two days later a drip infusion of 1,000 c.cm. of gum-saline to which was added 3 c.cm. of neptal was given, with a resultant diuresis of 160 oz. in 48 hours. Four days later a repetition of this latter measure yielded a similar result. The patient was considered fit for discharge on Oct. 23.

Fersolate, 2 tablets thrice daily, was prescribed on admission, but was inadvertently omitted for some weeks, and a Hb value of 60% was subsequently noted.

		Urinary Output in 48 Hours
July to Sept. ..	Various diuretic methods (including 2 c.cm. I.V. neptal)	Average 40 oz.
Oct. 8 ..	Test dose 50 c.cm. I.V. 6% gum-saline	30 oz.
Oct. 14 ..	1,000 c.cm. I.V. (drip) 6% gum-saline	40 oz.
Oct. 16 ..	1,000 c.cm. 6% gum-saline + 3 c.cm. neptal I.V. (drip)	160 oz.
Oct. 20 ..	" " " "	160 oz.

Comment

In a case of nephrotic nephritis, neither mercurial diuretics nor gum-saline injected separately promoted diuresis, but simultaneous infusion of both substances apparently produced a striking increase in urinary output. It is suggested that the simultaneous injection of mercurials with serum, plasma, or whole-blood transfusions might improve the otherwise poor results recorded in these cases by Brown, Gray, and Mollison (1942), using serum transfusions alone. From their findings these authors suggest that tissue fluid is drawn into the circulation during transfusion. It is possible that the simultaneous presence of mercurials in the blood might act effectively on the withdrawn tissue fluid in cases of nephrotic oedema. The frequent association of low haemoglobin values in these cases further suggests that whole blood might in certain cases yield better clinical results than normal serum or plasma, provided the addition of mercurials does not adversely affect the course of whole-blood transfusions.

I wish to thank Dr. L. Glick, assistant honorary physician to the Royal Halifax Infirmary, for permission to publish this case.

Reviews

OUT-PATIENT SURGERY

Surgery of the Ambulatory Patient. By L. Kraeer Ferguson, M.D., F.A.C.S. With a section on Fractures by Louis Kaplin, M.D., F.A.C.S. (Pp. 923; illustrated 63s.) Philadelphia, Montreal, London: J. B. Lippincott Company.

Under the rather unusual title *Surgery of the Ambulatory Patient* Dr. L. K. Ferguson of Philadelphia has written a comprehensive book of over 900 pages upon minor surgery. The scope of out-patient or minor surgery is always difficult to define, but the author's assurance that all the procedures mentioned have actually been carried out on ambulatory patients shows that the limits of such work have been respected.

It is pleasing to note that on the whole the treatments adopted are very like those in common use in this country, but the chapter which deals with the bites of poisonous snakes, the black-widow spider, scorpions, and ticks makes strange, if interesting, reading here. The field of minor surgery appears to have been well covered and there are accounts of many of the rarer and newly recognized conditions. Thus the curious "burrowing ulcers" described by Meleney receive notice; zinc peroxide, as originally advised, is successfully used in their treatment, as also of progressive gangrene of the skin (a condition, here called "progressive bacterial synergistic gangrene," which can hardly lend itself to out-patient treatment) after the wound has been excised surgically. Erysipeloid, due to the swine-fever organism and a commoner infection than is usually recognized, receives proper attention.

There is a useful chapter on foreign bodies and their removal, although we were surprised to find no mention of the peculiar injuries produced by the points of indelible pencils, since these are said to be more frequent in the United States than elsewhere. Two conditions which are notoriously difficult to eradicate—i.e., thyroglossal and pilonidal sinuses—receive special notice. Suitable radical operations are described, and in both instances the use of sclerosing solutions is stated to be well worth a trial. A very considerable section of four chapters on fractures is written by Dr. L. Kaplin, and here all fractures which are at all suitable for ambulatory treatment are adequately dealt with.

In testing the general comprehensiveness of the volume we looked up the subject of the suture of divided tendons, especially on account of the doubts which have recently been expressed as to the value of this procedure, anyhow in the case of tendons enclosed in sheaths. We were disappointed to find only the briefest of references to a subject which surely comes under the heading of ambulatory surgery. Division of tendons is common and often leads to great disability, so that its consideration should be granted much more space in any further editions. The general tone of the book is, however, extremely practical, and to this end there are over 600 useful illustrations; it is easy to read, well produced, and can be recommended with confidence.

BIOCHEMISTRY OF ACUTE ALCOHOLISM

Acute Alcoholic Intoxication: A Critical Review. By Henry W. Newman, M.D. (Pp. 207. $2.50 or 15s. 6d.) California: Stanford University Press; London: Oxford University Press.

The title of this monograph does not sufficiently stress the fact that it is a critical review of the biochemistry of acute alcoholic intoxication, and is indeed of the utmost practical and scientific value. A large proportion of the research on alcoholic intoxication during the past decade has been inspired by the increasing importance of the diagnosis owing to the widespread use of the automobile and the danger to society of both the intoxicated driver and the intoxicated pedestrian. Newman summarizes knowledge of the absorption and excretion of alcohol and shows that only about 10% is excreted in the breath and urine, and this fraction cannot be increased to any significant extent by therapeutic measures. The remainder of the alcohol undergoes combustion to carbon dioxide and water, the initial steps of this process taking place in the liver. A 70 kg. man cannot metabolize much more than a pint of 90-proof whisky in the 24 hours, and, though this quantity may be exceeded temporarily, it cannot be continued without interruption for any period without a lethal outcome; the fact that death does not more often occur from acute alcoholism alone is explained by the protective actions of coma and emesis. This amount of alcohol yields approximately 1,200 calories, which is a considerable proportion of the basal metabolic requirements. We cannot expect any therapeutic measure aimed at the removal of the alcohol by combustion to do more than double this, or more calories will be produced than the body can use, leading to an increase in total heat production. Combustion may be speeded up to some extent by fever, by increased protein metabolism, and by insulin. Although alcohol is a pharmacological antidote to strychnine and benzedrine, these drugs are of little use in treating acute alcoholism. Analeptics such as leptazol are of more value, while glucose, with or without insulin, increases the resistance of the nervous system to the lethal action of alcohol. Carbon dioxide is helpful for the respiratory depression.

The chemical diagnosis of alcoholism may be based on analysis of the breath, saliva, urine, cerebrospinal fluid, blood, or plasma. The last is probably the most reliable. In a complete review of this difficult and controversial subject, Newman points out that the effect of the same concentration of alcohol in the blood varies in different individuals. In one very well controlled study "the percentage intoxicated at each level of blood alcohol was enumerated as follows: 5–75 mg.% blood alcohol, 10.5% intoxicated; 75–125 mg., 18.5%; 125–175 mg., 47%; 175–225 mg., 83.6%; 225–275 mg., 90%; 275–325 mg., 95.1%; 325–375 mg., 96%; 375–425 mg., 98.3%; and over 425 mg., 100%. It can be seen quite readily that although the general correlation is definite, a great deal of individual variation in tolerance must exist to account for those individuals called drunk at low blood alcohol levels as well as those designated sober at very high levels." In addition, the reduction of driving ability below that of a reasonably cautious and prudent person depends not only on the amount of alcohol taken and in circulation and whether the concentration is rising or falling, but also on the previous degree of practice and skill. Hence, unless we decide to punish people for drinking alcohol at all if they are in charge of a car, we should probably regard a chemical analysis as only one item in the evidence, and in this connexion Newman stresses the importance of early examination by a physician, who may at the same time, if necessary, take a sample for analysis.

A CHALLENGE TO OBSTETRICIANS

Revelation of Childbirth. The Principles and Practice of Natural Childbirth. By Grantly Dick Read, M.A., M.D. (Pp. 262. 21s.) London: William Heinemann (Medical Books), Ltd. 1942.

This book accuses the medical profession in general and the consulting obstetrician in particular of gross mismanagement of all cases of normal pregnancy and labour. The early chapters are concerned with the anatomy of the uterus, pain-producing factors, and appreciation of pain. Next, the fear of childbirth is discussed together with its effect upon the neuromuscular mechanism of the genital canal. It is this effect which, according to Dr. Read, is responsible for the pain experienced during labour. He holds that labour should be painless, except perhaps during the final contractions of the first stage. These chapters do not make easy reading, and the simile between childbirth and defaecation is not convincing. The abuse of anaesthetics and analgesics in labour is then discussed, in which chapter there is much needless repetition. In fact, there is much redundancy throughout.

The most interesting part of the book describes the author's education of the pregnant woman, his treatment of her, both ante-natally and during labour. Here again he disagrees with orthodox teaching, for he believes that, in the early weeks of pregnancy, it is the retroverted rather than the anteverted uterus which will cause frequency of micturition. The chapter on relaxation would have been more appreciated before that on the conduct of labour rather than after it.

The end comes with an appendix consisting of a series of letters from patients reminiscent of advertisements for patent medicines. Yet, in spite of all this, no one can doubt Dr. Read's sincerity, and the book contains a message to all those who work in the field of midwifery—namely, that the physical condition is considered at the expense of the psychological and that neglect of the latter frequently converts what would have been a normal physiological function into a pathological process.

Notes on Books

In *My Self, My Thinking, My Thoughts* Mr. K. W. MONSARRAT makes a gallant attempt to analyse his own mental processes. In his opinion the present world crisis calls for a criticism of human habits of thought as an essential preliminary to a better state of affairs, and the first step must be a self-criticism. The book is not easy reading, even with the aid of the symbolic diagrams provided, and it illustrates the difficulty of conveying to others one's own methods of thought. In the chapter on sociology the author adopts the Adlerian philosophy; the general reader will probably be most interested in his view that the attraction of the mystery religions lay in their providing an antidote to fear. The book is published at 7s. 6d. by the Liverpool University Press, and in London by Hodder and Stoughton.

Although the editors of *The 1941 Year Book of Radiology* (H. K. Lewis, 27s. 6d.) have had to rely, because of the war, on radiological work done in the Western Hemisphere, the standard of this publication has been well maintained. As before, it appears in two sections—Diagnosis, edited by Dr. Charles A. Waters assisted by Whitmer B. Firor; and Therapeutics, by Ira D. Kaplan. In the section on diagnosis articles of interest are those on injuries from metrazol therapy, osteoporosis from circulatory obstruction, and insidious fractures from repeated mild trauma. Georg Brandt's paper on this is comprehensive and of considerable importance in wartime. The value of tomography in sinus disease is pointed out in a paper by Sherwood Moore and Cone, which also records two cases of enlargement of the internal auditory canal from VIIIth-nerve tumour, demonstrated tomographically. In the gastro-intestinal section there are interesting articles on *x*-ray control in the use of the Miller-Abbott tube in intestinal obstruction and on the small intestine in sprue and deficiency diseases. There is a report on the use of pheniodol for cholecystography. In the radiotherapy half of the book there is reviewed a wealth of articles on research in cancer and on general principles of radiotherapy and technique in individual systematic treatment. The editors and publishers are to be congratulated on the continued excellence of this yearbook, which is doubly welcome in these times of stress, when original papers are difficult of access. No radiologist should be without it.

A sixth edition of TORALD SOLLMANN'S *Manual of Pharmacology* has been published by W. B. Saunders Company at 45s. This well-known manual, which in our last review we described as "the fullest work of reference . . . written in English," is modestly introduced by the author in his preface as "a rather comprehensive outline of current knowledge and conceptions of drug actions, especially from the point of view of their practical importance in medicine, therapeutics, and toxicology." So much has happened since the preparation of the 1936 edition that the author has found it necessary not only to add new sections on such items as the sulphonamides, but also to rewrite almost every paragraph. This, as he says, has been made necessary by the fact that, in addition to the spectacular advances that have been made, there have been "quiet developments in nearly every field of medicine." To make room for the new material, and so as not to increase the size of the volume unduly, matter which was becoming out of date has been either omitted or condensed: the author has wisely decided to omit the section on specific sera and vaccines. Sollmann's *Pharmacology* is not only an indispensable reference book; the matter set in large type provides a continuous narrative that serves as a text for the student. The volume is completed with 104 pages of bibliography which has been "checked repeatedly to increase its accuracy."

Studies in Hay Fever and Asthma records a series of investigations undertaken by Dr. DAVID HARLEY during the tenure of an Asthma Research Council Fellowship, 1932-9, in the laboratories of the Inoculation Department, St. Mary's Hospital, London. The work represents advanced studies of a chemical and immunological nature dealing with the substances concerned in allergic reactions and in the mechanism of specific desensitization. Hence the work is of more interest to the specialist than to the practitioner. Many experiments are detailed to show the differences between the hay-fever idioceptor and anaphylactic and other antibodies, and in investigating the chemical nature of the hay-fever idiotoxin the strongest reactions were obtained with a fraction which contained denatured protein of albumin type. The role of heredity in hay-fever is discussed, and Harley considers it connected with the inability of the blood to digest certain constituents of the pollen grain. In the specific diagnosis of hay-fever it is stated that "for routine purposes it is sufficient to make a test with Timothy (Phleum pratense) pollen extract," a statement with which most other observers will not agree, and the possibility of other sensitizations in "seasonal" hay-fever cases is not mentioned. The book is published by William Heinemann at 10s. 6d.

Messrs. H. K. Lewis and Co., 136, Gower Street, W.C.1, publish on behalf of Dr. S. L. SIMPSON a simple scheme of instructions for measuring insulin as used at the Willesden General Hospital diabetic clinic. The front page of the card contains the instructions and at the middle opening there are illustrative diagrams. The publishers will send a specimen card on receipt of 8d.

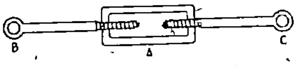
Preparations and Appliances

FRACTURE OF BOTH BONES OF LOWER LEG: A TRACTION APPARATUS

Surgeon Lieut. W. A. HUTTON, R.N.V.R., writes: The method of choice in the reduction of lower leg fractures associated with overriding lies in skeletal traction with plaster fixation. Recent suggestions that this is productive of delayed union have not been supported by our experience. The apparatus described below was devised when simplicity with ease of construction was essential; it has been found competent to deal adequately with any of these fractures, and it is considered that in certain respects it is an improvement on existing methods.

Apparatus.—Primarily this is a bottle-screw traction of common engineering practice. At one end of each of two metal rods of arbitrary length is bent a metal loop, and at the other end of each rod a thread is cut. In one rod this thread is left-handed and in the other right-handed. A metal bottle-screw bridges the rods across the threaded extremities. By rotation of the bottle-screw the ends of the rods can be approximated or separated, according to the direction of rotation.

Operation.—The loop at the end of one rod is attached to the lower fractured fragment; the loop at the end of the other rod is attached to a fixed point. In our case this fixed point is a metal hook cemented into the theatre wall some six feet from the ground. Under local anaesthesia a Steinmann pin is inserted through the lower tibia or os calcis and the stirrup connected; the remaining metal loop is then connected to the stirrup by means of the Steinmann pin. The table is tilted to the Trendelenburg position to provide the counter-extension of the patient's body weight. Traction is now applied by rotation of the bottle-screw, which is controlled radiographically.



A=Bottle-screw. B=Loop attached to a fixed point. C=Loop attached to skeletal traction.

After overriding has been corrected, and apposition obtained by lateral pressure, two flannel strips are passed under the leg, the one at the fracture level and the other below; a third may be passed under the knee-joint if thought necessary. The bottom flap of the table is then dropped, an assistant supporting the limb by means of the flannel strips. A posterior plaster slab is applied from the plantar surface of the foot to mid-thigh, passing through the stirrup and incorporating the posterior portions of the flannel strips. When this has set, the assistant supports the limb by the cast, the redundant pieces of flannel are cut away, and the plaster completed in the usual manner. When the cast has firmly set the extension is removed and the patient returned to bed, with application of weight extension if the type of fracture renders the reduction likely to be unstable. To prevent rotatory stress on the fragments, the plaster is renewed or wedged around the knee-joint in slight flexion previous to the fitting of a walking-iron.

Summary.—The points in which it is suggested this apparatus is of value are: (1) It is very simple and cheap, and can be constructed, as in our case, in a non-technical workshop. (2) The traction is applied with the knee extended, avoiding the necessity for completing the plaster in two portions, the one with the knee flexed and the other with the knee extended. Loss of the reduced position has been noticed when the limb is straightened to complete the plaster. (3) The operator has ample room in which to complete the plaster, there being no traction apparatus near the limb. (4) The rate of reduction is very gradual, and when obtained the reduction is positive, there being no possibility of any slip-back. It is under radiographic and mechanical control throughout.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY SEPTEMBER 26 1942

A NUTRITION COUNCIL

The well-informed article that appeared under the main heading of "Food and Food Values" in the *Times* of August 28 is welcome for more reasons than one. The medical man, and other workers in applied science, have for long deplored the apathy towards, and ignorance of, science, and especially biology, that exist not only among the general public but in particular among educated men and women. In peacetime it was a common criticism in the world of science that those who were in charge of the destinies of this country, and especially the civil servants responsible for the day-to-day administration of Government policy, were lamentably ignorant of those scientific facts and principles upon which the material world in which we live is largely hinged. Since the outbreak of war recurrent protests from workers in various branches of science have borne witness to the frustration felt by men who understand what is meant by the hackneyed phrase, "We live in an age of science," when they observe the recurrent stupidities committed by civil servants educated in the classics and the humanities. We believe that, in overcoming the apathy and ignorance that still exist, organs of responsible opinion such as the *Times* have an important part to play, and it is therefore with pleasure that we see published in its columns an article referring to such matters as "the microscopic examination of the eye." and "blood and urine analysis." There is a real potential interest in biological subjects, and so in medicine—especially when applied to the prevention of disease—that is still largely unsatisfied, and until this is satisfied it will not be easy to arouse public interest—and so promote public action—in the proposal made in the *Times* article that a Nutrition Council should be formed.

The first question to be decided is whether there is need for such a council. The arguments adduced in the article referred to are very much in line with discussions that have taken place during the war on the need for the unification of the medical services. As the *Times* correspondent points out, there are a number of bodies concerned in some way or other with nutrition. For example, there are the Medical Research Council, the Ministry of Food, the Ministry of Health, the newly formed Nutrition Society. There are the Board of Education, the Ministry of Labour and National Service, the Agricultural Research Council, the Food Investigation Board, the Department of Scientific and Industrial Research, and the Cabinet Advisory Committee on Food Policy. There are, too, the food manufacturers and the caterers. At the moment the country is very "food-conscious," and everyone is acutely aware of the fact that, in the main, the stomachs of the nation are filled with produce brought to this country by ships which have to run the gauntlet of the enemy submarine and surface raider, and that even if we produce the maximum amount of foodstuffs that can be home-grown we must, as a small island with a large population, depend for our sustenance largely upon what comes from other countries. This in itself has recently brought to the fore the important technical problem of dehydrating foodstuffs, so that the holds of ships shall be occupied by what is essential and not by the large quantities of water which the natural food contains. Again, the shortage of citrus fruits has focused attention on the technical problem of canning and cooking vitamin-containing foods so that these vital factors of diet are not destroyed. The most enlightened Government Department thrown up by the war, the Ministry of Food, has played a fine part in bringing home to the consciousness of every man and woman in the country the multitude of factors that enter into providing them with the kinds and amounts of foods that are necessary to keep body and soul together. What is more, it has stirred an interest in nutrition as the basis of good health and has created a demand for good and sufficient food that the people of the country will insist upon having satisfied when this war is over.

With so many diverse interests involved, with so much technical information that is ill co-ordinated, there would indeed seem to be a sound case for forming the proposed Nutrition Council. If this is granted, the next question is whether any of the various organizations referred to above is by its present constitution fitted to fulfil the function of such a council. It seems obvious that the work should not be undertaken by any Government Department which has at its head a Minister who, whatever else he is, is first and foremost a politician. In a letter to the *Times* Lord Dawson suggested that "the Medical Research Council is designed for just such a purpose, as its record will show." We need not remind readers of the valuable work done by the M.R.C. in the field of nutrition as well as in all other fields of medical research, or remind them of the high position in the world of nutritional science held by its present secretary. But as its function under the Privy Council is limited to medical research, and as in the conduct of a food policy for the country as a whole so many non-medical sciences are involved, not to mention the key position of agriculture and the contributions of economists and statisticians, it may be doubted whether the task is one that the M.R.C. would be anxious to undertake. We come, therefore, to the other proposal made in the same newspaper by Lord Horder—namely, that the Nutrition Council should itself be a committee of the Privy Council; and this seems to meet the "logic of the situation."

The Nutrition Council should first and foremost act as a bureau of information, and its first task should be to collect and collate all the information from the various sources that exist, from ministries, research organizations, individual research workers, clinicians, medical officers of health, dietitians, biochemists, food chemists, food manufacturers, agriculturists, economists, and even perhaps from food tasters. Once existing information had been assembled and card-indexed, the second task of the Nutrition Council would be to discover the existing gaps in knowledge and to arrange these in order of importance so that research workers could be encouraged to tackle first those problems the solution of which is of first importance to the health and well-being of the people. The research worker, whether he wants to follow his own bent or whether he is encouraged or directed to pursue a certain line of inquiry, often enough finds at the end of his task that he has wasted a lot of time in going over the same field as other workers. The Nutrition Council should be able to make the individual worker or research organization fully acquainted with the work in progress on any particular subject. The third function of the Nutrition Council would be to initiate research along co-ordinated lines among the various sciences that converge on the kitchen table.

All this is not to suggest that nutritional research should be controlled by an authoritarian body. All fundamental research is, we believe, carried out by exceptional individuals whose instinct of curiosity fastens itself on to subjects of peculiar interest to their own genius. But it is idle to deny that much scientific research has been determined by motives other than those aiming at the welfare of the consumer. Research into processing, canning, and bottling, into methods of marketing, etc., may be directed to forming tastes and habits of diet that benefit the manufacturers and producers but not the consumer, and as medical men our primary concern is that the food eaten should maintain and improve health. The results of research in the food industry are often kept secret or protected by patent, and in such a matter as the large-scale manufacture of vitamins an essential process may be the close preserve of one company to its own commercial profit and the detriment of the world-wide consumer. How powerful commercial influence can work against the health of the community is well illustrated by the successful opposition in this country to pasteurization of milk, and the opposition to the introduction of wholemeal flour. One way to remedy these abuses is to bring them into the light of day and to broadcast the facts to the public in season and out. This could be done if the Nutrition Council had a publicity department with power to advertise in the Press and to use film, radio, and booklet to inform all and sundry of the facts about food—in other words, to follow in time of peace the excellent example set by the Ministry of Food in time of war.

There is need not only for a national clearing house for information but also for an international one, and, whether or not the Health Organization at Geneva is resuscitated after this war, there would seem to be a good case for the establishment of nutrition councils in all civilized countries to be linked up in one international establishment. In this way it should not be impossible to build up a social order in which the hungry and ill-nourished man in a world of plenty becomes a legend of the past.

BOVINE TUBERCULOSIS

Vital statistics of England and Wales in 1941 showed[1] a considerable increase in tuberculosis mortality among children. Such an increase may be caused by greater opportunities for infection with the tubercle bacillus derived from either human or bovine sources, or from both. In this war the incidence of bovine tuberculosis in childhood might rise because of less efficient control of tuberculosis in cattle and of milk or because evacuated children used to pasteurized milk were unable to obtain this in smaller urban and rural districts. To investigate the relative part played by each type of bacillus involves analysis of both respiratory and non-respiratory deaths in relation to towns and country districts, and bacteriological typing of organisms derived from cases of tuberculosis. Examination of mortality figures suggests at all events that the increase in incidence of tuberculosis among children cannot entirely be accounted for by bovine infection. But even in peacetime bovine tuberculosis took a great toll from childhood in deaths and disease, and measures to control this were generally recognized to be inadequate. About 30% of all cases of non-pulmonary tuberculosis in Great Britain are caused by the bovine bacillus. At all ages it is responsible for about 6% of deaths from tuberculosis (all forms); but this figure is much higher among infants and children than among adults. In 1937 Stanley Griffith considered[2] that "the latest findings in regard to this intractable problem should be made widely known, since they prove beyond any doubt that bovine tuberculosis is a serious menace which must be fought with the utmost vigour." He thought "the apathy of public opinion in this respect is astonishing in face of the incontrovertible evidence which has been published during the last quarter of a century. . . ."

Tuberculosis is widespread among cattle in this country, and much milk sold to the public contains live tubercle bacilli. It is generally believed that before the war about 40% of cattle reacted to the tuberculin test. This is a rough "average figure." As H. T. Matthews pointed out at a recent discussion at the R.S.M.,[3] there are districts in Britain where this incidence is nearly 100% and others where it is correspondingly low. Thus, using the tuberculin test, Montgomerie and Rowlands found 11.8% reactors in a North Wales district, Thomas 2.6% in South Wales, and Rabagliati 7.6% in a part of Yorkshire. Matthews rightly insists that "the conception of a uniform 40% incidence as a total bar to the application of American methods [slaughter, with compensation to owners, of all reactors] is therefore misleading." S. R. Gloyne stated that, in his laboratories, among 1,560 mixed samples of milk (mostly collected in the Home Counties), which were examined in 1928-31 tubercle bacilli were demonstrated in 9.1%; in 1935-9 this figure fell to 6.2%. He thought that at the outbreak of the war the incidence had probably fallen to about 4%, but there had occurred "a disturbing increase" in the figures since then. Examination of milk from individual herds has in the past shown that over 6% of all farms were sending out milk containing tubercle bacilli; it can be inferred, therefore, that nearly all bulked milk when mixed from twenty or more herds is likely to be infected.

In 1937 the Ministry of Agriculture introduced the Tuberculosis (Attested Herd) Scheme to encourage milk producers to eradicate tuberculous infection from their herds; and in 1939 about 3% of the dairy farmers in the country had had their herds attested. No progress in this policy could be made since the outbreak of war. Clearly this method is somewhat laborious and costly, and time must elapse before success can be achieved. This depends on the frequent and accurate use of the tuberculin test, which has in the past not always been carried out with either a satisfactory tuberculin or a satisfactory technique. Gloyne[3] pointed out that even among the specially designated milks tubercle bacilli could be found in nearly 1%. Prof. T. Dalling deplored that no provision is made for the disposal of cattle that react to the tuberculin test, so that in the clearing of a herd of tuberculous infection by the use of the test many infected animals may find their way to open markets and in their turn create new sources of infection or even perpetuate infection in herds throughout the country. Nevertheless, he thought "the eradication of tuberculosis from a herd or group of animals and the prevention of further infection is the ideal method of control." R. F. Montgomerie considered that to "segregate our infected animals from our clean" was the correct policy for this country. He added, further, that "the greatest hindrance to the establishment of tuberculosis-free herds is due to the apathy of the public in not demanding milk from tuberculosis-free herds and in not being prepared to pay a fair price for it." H. J. Parish insisted that if milk containing dangerous organisms had been sold to the public surely it was not the public but the Government Departments concerned which were responsible.

Opinion on the beneficial effects of B.C.G. vaccination in cattle is still divided, and the immunizing properties of the recently discovered vole bacillus are still under experimental investigation. On the whole, therefore, little progress is likely to be made in the eradication of tuberculosis in cattle while the war continues. The solution of the related problem in man must therefore be sought in pasteurization, which should be compulsory not only because of tuberculosis but also because of the number of other infections spread by milk. But pasteurization must be efficient. Gloyne found that 2.5% of 276 pasteurized samples contained tubercle bacilli. In discussing the Milk (Special Designations) Regulations, 1941, we pointed out[4] that the widespread use of the phosphatase test by authorities controlling licensed pasteurization plants had in the previous two or three years shown that in an alarming number of cases the terms of the licences had not been observed. The 1941 Regulations permit local authorities to grant licences to use the special designation "pasteurized" in respect of milk processed also by "high-temperature short-time pasteurization." The differences between this and the holder system are that at no time is the flow of milk actually arrested, and the margins of safety are less in terms of absolute time and temperature and demand great precision in control. It is evident that this Order, which is considered provisional and justified by the abnormal times, requires even more skilled working and an even more well-informed and technically minded inspectorate than before. We hope that these are available or are being trained for extension of pasteurization. In the meantime we note with pleasure that the Chief Medical Officer of the Ministry of Health recommends that for children all milk which has not been pasteurized should be boiled.

PHARMACOLOGICAL PROPERTIES OF SERUM

The great stimulus of the war to a fresh search for the perfect blood substitute has once again aroused interest in the possible value of serum. From the technical point of view serum has the advantage of being filtered more easily than plasma, but otherwise there is little difference between the physico-chemical characteristics of the two. So the main controversy has turned on whether the side-reactions produced by serum are so serious as entirely to invalidate its use. Toward the end of the last century the presence of a vasopressor substance was demonstrated in serum, to which the name "vasotonin" was given.[5] [6] And the earlier workers were able to show that this substance appeared in connexion with the process of clotting and was not adrenaline. Stewart in 1913 and subsequent workers have associated it with the presence of blood platelets, though others believed that the vasoconstriction was really due to the blocking of capillaries with minute particles. In addition to the "vasotonins" there is evidence that freshly prepared serum contains a vasodilator substance, considered by Zipf to be an adenyl derivative, and also some other substance which Brodie in 1900 found would cause a profound respiratory and cardiovascular depression in cats.

Reid and Bick[7] have confirmed and extended some of these observations. They found that the vasotonins, which would cause contraction of isolated strips of ox carotid and guinea-pig jejunum, and so could not act by virtue of their particulate nature, could be eliminated in the preparation of serum by any procedure which will remove the platelets, such as the recalcification of plasma which had been centrifuged or "cream-separated." Platelet extracts, on the other hand, were vasoconstrictor. The vasotonins passed through cellophane membranes and could be dried, stored, and were thermostable. No adenyl compounds were detected, as the serum used was always at least 12 hours old and contained an enzyme which inactivates adenosine. In the dog and rabbit serum injections were without ill effect, but in the cat experiences similar to those of Brodie were recorded, in which a few cubic centimetres of even homologous serum caused a profound fall of blood pressure, sometimes followed by death. This was attributed to pulmonary and coronary vasoconstriction, and the substance responsible was found only in platelet-rich serum; it was not the same as vasotonin, for it was destroyed by heat, and was not dialysable or ultra-filterable. These facts are being used in Australia to produce a serum which is free from pharmacological disadvantages. By keeping it for 12 hours any adenyl compounds are destroyed, and by removing the platelets the vasotonins and the substance responsible for collapse in the cat are removed at the same time. The fact that serum possesses practical advantages over plasma from the point of view of preparation should encourage the trial of these methods. The final decision must depend on clinical experience, and what there is does not exclude the use of serum as an efficient substitute for blood.

MATERNAL PULMONARY EMBOLISM

Maternal death has a tragic poignancy unique in human experience. The feeling of hopelessness which all in attendance experience at such a time is not lessened by the diagnosis of "obstetric shock" for which on occasion no satisfying explanation can be offered. An excellent paper by Steiner and Lushbaugh[1] throws new light on the subject of sudden maternal death, and raises the possibility that in the future at least some of these deaths may be prevented. They maintain that the most common cause of death during labour and the first few hours that follow it is the occurrence of pulmonary emboli due to the passage of meconium, liquor amnii, and vernix into the maternal circulation. These findings were based on an analysis of the clinical histories and post-mortem material of 72 maternal deaths investigated in the department of pathology of the University of Chicago. In eight cases the evidence suggested that death was due to the passage of emboli of foetal origin into the maternal circulation. The clinical picture revealed by analysing the case histories was a fairly constant one. Uterine contractions tended to be violent, with actual tonic contraction in two cases. Then suddenly a rigor occurred, or the patient complained of feeling cold and passed into a state of shock. This was characterized by restlessness, dyspnoea, cyanosis, low blood pressure, and, on occasion, vomiting and delirium. Two of the eight patients died undelivered, and all were dead within 12 hours of the onset of symptoms. In the small series studied, all but one patient was parous and four of the infants had died before labour began. Necropsy revealed a characteristic pathological picture. In seven of the eight cases there was macroscopic pulmonary oedema with no visible emboli in the main pulmonary vessels and no evidence of infarction. The striking changes were found on microscopical examination of the lungs, when emboli were seen in the smallest pulmonary arteries (those with a diameter of less than 1 mm.), arterioles, and capillaries. These emboli consisted of epithelial squames, amorphous debris identified as vernix, and mucin identified as meconium. In a control series of 34 patients who died after the 7th month of pregnancy and before the 7th day of the puerperium the changes described above were not discovered. In view of this it would appear that these emboli were associated with the clinical picture of shock in the series recorded. Further evidence was collected from experimental studies on dogs and rabbits. By injecting intravenously meconium and amniotic fluid the authors made the following important observations: the animals could be killed by the injections, and when this took place the clinical picture was one of anaphylactic shock. In this connexion it is interesting to note the observation made by DeLee[3] that in women who die unexpectedly during labour or just after it, and in whom no cause of death can be found at necropsy, the picture resembles that of anaphylactic shock. If death of the animals did not happen too rapidly pulmonary oedema developed. Post-mortem examination revealed changes in the lungs similar to those found in the 8 patients who had died. As a result of these investigations the authors claim that they have established the identity of a new disease with distinctive aetiology, symptomatology, and pathology. The criticism could be made that the evidence in support of this claim was collected from a very small series of cases, but none the less it has been very carefully and critically analysed. Now that attention has been drawn to the condition there is certain to be a more careful study of cases presenting the syndrome, and the accumulation of further facts cannot be long delayed.

THE AETIOLOGY OF PHLYCTENULAR OPHTHALMIA

The provision of the White Oak Hospital by the London County Council for the care of children with eye affections requiring prolonged treatment is of great value. It is a real regional provision for eye cases. Children were admitted at first for trachoma. Now this affection is rare, so the beds are available for other cases. Mr. Arnold Sorsby has worked in this hospital as the ophthalmologist for several years, and his work and observations on cases of phlyctenular ophthalmia were the basis of his Hunterian Lecture at the Royal College of Surgeons in January of this year. In the *British Journal of Ophthalmology* of April and May his observation and those of many workers are set out. He has made an excellent review of historical research on this disease, but the greatest interest is centred in his own observations. The records cover 16 years and 1,392 children, of whom 39.1% were boys and 60.9% girls; in other cases of eye disease admitted the sex incidence was roughly equal. He found no obvious difference in the state of nutrition in the phlycten cases, nor any material difference in the incidence of focal sepsis and pediculosis. Reactions to non-bacterial allergens (derivatives of milk and egg, house dust, dandruff, pollens, etc.) were negative. The positive reactions were obtained by the testing with tuberculin. All the children were so tested for 16 years: children over 6 years of age by the Mantoux test, those under 6 by the Moro test. Positive reactions were obtained in 84.8% of all phlycten cases; whereas the corresponding incidence in cases of blepharitis was only 15.3%. Radiography of the chest in 510 cases showed that there was evidence of tuberculosis in 72.2% of phlycten cases—nearly 9 times more than in the controls. Clinical tuberculosis was seen in 6.4% of phlycten cases, against no cases in the controls; and a family history of tuberculosis in 28.9%, against 3.7% in the normal school population. The blood sedimentation rate was raised to 79.8% in active phlyctens, against the normal rate in others. Tubercle bacilli could not be recovered in stomach washings or in excised tonsils. The after-histories of ten years of cases showed an incidence of 5.3% of clinical tuberculosis and a mortality rate of 0.8%, about 5 times the incidence in the controls. Mr. Sorsby writes: "It is therefore concluded that phlyctenular ophthalmia is a manifestation not of tuberculous disease but of tuberculous infection, the phlycten making its appearance only when a hyperallergic phase is present and there is a suitable (? specific) exciting factor of endogenous or exogenous origin."

There is one point that arises in the consideration of this excellent report of observations and records of Mr. Sorsby. Why should the eye be attacked and damaged by this strumous bodily reaction and condition? This report gives no hint of an answer to this question. One observer (Harman: *The Conjunctiva in Health and Disease,* 1905) found some evidence in the acute cases seen in a children's hospital of a hint of an answer to this question. The position of the fresh acute lesions seen during ten years was marked on charts. The tabulation was conclusive. The limbus in the temporo-malar quadrant was the seat of election. The limbus has the most delicate nerve supply of the whole conjunctiva, and in this quadrant there is a direct connexion with the nerves of the teeth of the upper jaw. There is much dental irritation in children of the age group of the incidence of phlyctens. The serious general bodily affection by some tuberculous infection, so conclusively demonstrated by Mr. Sorsby, would render this seat of possible dental irritation particularly sensitive. Mr. Sorsby concludes: "The prognostic significance of the phlycten is graver than that of a positive tuberculin reaction in a child; this is borne out by the subsequent incidence of tuberculosis and mortality from it in children previously affected with phlyctenulosis." So this eye disease is in a sense an indication of the grade of physical fitness or unfitness in children.

ESSENTIAL FRUCTOSURIA

Among inherited human anomalies of metabolism essential fructosuria must be one of the rarest and, at the same time, in all probability one of the most harmless. In this condition a definite and constant part of the fructose ingested, about 13%, is excreted unchanged in the urine, and this is found whether the fructose is ingested as such or results from the breakdown of cane sugar. The usual tests do not differentiate fructose from glucose, and affected persons are usually supposed, until more careful investigation is made, to be cases of ordinary glycosuria. Margaret Lasker[1] has made a very extensive study of the anomaly and has greatly amplified the sparse knowledge collected during the 64 years since the condition was recognized. Some idea of its rarity may be gathered from the fact that she has been able to collect no more than 58 cases from the literature, and, of these, 18 do not satisfy the requirements for positive recognition. The incidence of fructosuria is probably considerably less than one in a million. Lasker, as the result, obviously, of a prolonged search and with the co-operation of other physicians, has added no fewer than five families. Recessive inheritance is clearly indicated. In four out of her five sibships containing affected persons the parents were blood relatives, and this is true of two others reported previously. In the other recorded families no statement was made on this important point. The proportion of affected among the brothers and sisters of those persons who brought the families to notice is sufficiently close to the theoretical one in four. In the comparatively few instances in which parents or offspring have been tested they have invariably been found to be normal. The harmless nature of the condition is indicated by the fact that, although accompanying departures from normality have often been described, these are nearly always different and seem to be associated only accidentally with the fructosuria. Lasker's paper performs a service in summarizing the literature, in adding valuable original material, and in clarifying this small by-way in medicine.

DYSENTERY AND DIARRHOEA IN WARTIME

BY

Sir P. H. MANSON-BAHR, C.M.G., D.S.O., M.D., F.R.C.P.

(*Concluded from p.* 348)

Treatment of Bacillary Dysentery

The first thing to be said about treatment is that the sooner the disease is diagnosed and treatment commenced, the better. At the beginning of the last war patients were given opium and opium pills—a pernicious practice; but when the patient is being transported over long distances morphine or tincture of opium may be given to keep him quiet, and to stop the violent peristalsis, dysuria, and tenesmus. "*Saline treatment,*" introduced by Army surgeons 300 years ago, has still the greatest vogue. Large doses of the salts are given. Some like senna, others rhubarb; but I myself believe that there is nothing better than sodium sulphate, 1 drachm every three hours for the first forty-eight hours and then four times daily until the stools become faeculent, because at first they contain no faeces at all.

Diet is most important. Do not starve your patients. There is no sense whatever in that system, for the upper small intestine is still functioning, and so is the stomach. Not much milk must be given, because it forms into clots and curds, which are passed with difficulty. They should have large amounts to drink—four or six pints of lemonade or barley-water—to replace dehydration. They can be fed on junket, jellies, beef-tea, and chicken broth. In America ice-creams are in vogue. Do not attempt to give anything solid like milk puddings or sago until the stools contain faeces. Above all things, arrowroot is suited for the treatment of bacillary dysentery. The natives of the Pacific have treated dysenteries with arrowroot since time immemorial. The addition of brandy is stimulating and comforting.

Recently it has been shown that blood transfusion is an excellent measure in desperate cases, and has recently been employed in a big outbreak of dysentery in Poland. The other measure is intravenous hypertonic saline with 5% glucose. Then we come to antidysenteric serum, about which a number of doubts have recently been expressed. The real trouble arises from the fact that the antidysenteric serum of the last war was polyvalent, but now we have a concentrated form of Shiga serum. The cases that require serum treatment are Shiga infections. You do not have to wait until your laboratory diagnosis has been perfected before acting, but serum must be given early and in sufficient amount—i.e., 80 c.cm. intramuscularly to adults. The muscles of the buttocks are suitable for the purpose, also the adductor muscles of the thigh, but it should not be injected subcutaneously. Many a soldier has told me he would rather put up with his dysentery than with subcutaneous serum. Serum sickness, which can be obviated by injections of adrenaline, commonly ensues. In severe toxic cases serum can be given intravenously in doses of 50 to 60 c.cm. Anaphylaxis is apt to occur in bacillary dysentery with antidysenteric serum, especially if the patient has been sensitized to it previously, but not many die from this cause. But please do not give everybody antidysenteric serum indiscriminately. The majority of cases get well without it. I think it is a very good rule to say that, if the patient is very toxic, if his pulse rate is about 120, if his temperature is 103° or 104° F., and if the stools number more than twelve in the twenty-four hours and contain a lot of blood and slime, then antidysenteric serum should be given, but otherwise not.

Chronic bacillary dysentery is not so easy to treat. The best method is irrigation of the large intestine with eusol—1 part to 5 parts water. This can be injected into the large intestine, but some of these cases do not respond at all, and a valvular caecostomy may have to be performed to put the bowel at rest. The whole problem of treatment of the bacillary dysenteries, in both the acute and the chronic stages, has now been transformed by the introduction of sulphaguanidine, a sulphonamide which is specific for dysentery bacilli and is given in doses of 6 to 9 g. daily for the first five days; reports on this subject are now coming to hand. It really seems as if this drug was specific, especially for Shiga and Flexner infections. It is also curative in the chronic form.

The best way of diagnosing bacillary dysentery is to examine the exudate under the microscope. Clinicians used to say that if you had to wait for the laboratory to give the correct diagnosis the patient would have either recovered entirely or have succumbed. Nevertheless, a pretty accurate forecast can be made from a study of the cellular exudate. Sigmoidoscopy is a useful adjunct.

In chronic bacillary dysenteries the whole of the mucous membrane is covered with granulation tissue. The normal folds have disappeared and the walls are thickened and stenosed. Therefore stenosis of the bowel is a feature of the post-dysenteric state. This occurs after bacillary dysentery; never after amoebic. Sometimes masses of granulation tissue form and are known as pseudopolyposis, similar to that of chronic ulcerative colitis.

Amoebic Dysentery

Great emphasis has been laid on amoebic dysentery, but it is not anything like the danger it is stated to be. Dobell has claimed that *E. histolytica* infection is the most easily controlled of any in man. This protozoan produces ulcers of the large intestine, but apparently it is a question here of a struggle between the processes of repair and those of destruction. The *E. histolytica* is a parasite of the submucous layer of the large intestine; it lives mostly beneath the surface and not above. It may be looked upon as a sort of intestinal "rabbit," and the first lesions visible are little superficial abscesses on the mucosa which indicate its burrows. If one of these be incised there exudes some grumous material containing active *E. histolytica.* Although these lesions are scattered throughout the length of the intestine, the intervening mucous membrane is perfectly normal. A familar form of lesion is known as the "sea anemone" ulcer. It will be observed that fissures traverse the bowel, and there are blood-stained sloughs hanging down like seaweed. Sometimes multiple ulcerations or solitary ulcers of large size are present. The clinical phenomena of amoebic dysentery are produced by local lesions of the intestinal canal. Thus the two main dysenteries are as unlike and apart as the two poles.

There is no mistaking the *E. histolytica* for anything else when it is seen under the microscope. The difficulty always is that it may not be present in the particular portion of the stool when examined. This parasite does not live very long outside the human body—in the tropics perhaps two hours, in this country perhaps three or four. It is most important to examine the stools as quickly as possible. In a fresh specimen the active *E. histolytica* moves, as Dobell says, "like a slug at express speed." Each individual has the characteristic nuclear granular endoplasm and clear marginal ectoplasm, and it lives upon red blood corpuscles. What the oyster is to the alderman the red blood corpuscle is to the *E. histolytica*! Sometimes as many as 60 or more may be found inside one individual. Then there are in the exudate Charcot-Leyden crystals. But do not jump to the conclusion that these crystals necessarily mean amoebic dysentery: they are found in all kinds of infections of the large intestine, especially ulcerative colitis, but they are certainly common in association with amoebic dysentery.

Amoebic dysentery may produce astonishing situations. In 1937 a man who had had an appendicostomy wound since 1900 was seen. He had been washing himself out daily with 7 pints of fluid, but in the stools one *E. histolytica* was found. He was then rapidly cured by anti-amoebic treatment and the wound rapidly healed. Amoebic dysentery may present amazingly long incubation periods. There was an old lady aged 74 with a liver abscess for which she had been operated upon. When the stools were examined she proved to have a heavy infection with *E. histolytica,* and the organism was also present in the pus from the liver abscess. On probing into her history it was found that the only time she had been abroad was when, as a bride aged 17, she went out to Bombay for ten days and had had some intestinal disturbance there. The incubation period in her case was approximately fifty-seven years! Another case was that of a man who was playing tennis at Wimbledon and went down with acute dysentery, which was thought to be ulcerative colitis. I could not find the amoebae in the stools; but his intestinal canal was full of typical ulcers, and in scrapings made from them *E. histolytica* was discovered in large numbers. He had lived in Mauritius till he was 4 years of age, and was then 27. Not very long ago a man was sent to me as a case of carcinoma of the rectum. He had a large fungating rectal ulcer. During the last war he had had dysentery on the Somme in 1916, but had not noticed anything until, after eating some fried fish, he passed blood and mucus in the stools and was taken to hospital, where the ulcer was scraped and found to contain *E. histolytica.* In other words, the disease had taken from 1916 to 1937 to develop.

The chronic stage is different from the acute. These people generally suffer from flatulency, from abdominal pain, and from periods of constipation alternating with diarrhoea. The cysts which are found in the chronic stage have four distinctive nuclei; they stain with iodine, which shows up the chromatoid body in their interior. But the cysts of *E. coli* are also found in the stools, and it is necessary to differentiate one from the other. Sometimes four nucleated cysts are present, but the patient does not show any symptoms of acute disease at all. These cases are known as "cyst passers" or "cyst carriers." In India the cyst-carrier rate varies from 60 to 15%, in the United States about 10%. There was a great epidemic of amoebic dysentery in Chicago a few years ago—one of the most remarkable epidemics of all time. Two big hotels were implicated. It was proved afterwards that *E. histolytica* was present in the drinking-water. One of the drains was infiltrating into the main water supply. Thus it was proved that amoebic dysentery is a water-borne disease. The incubation period is anything from 2 weeks to 120 days. We know that the *E. histolytica* may lie dormant for a long time inside the body without producing any outward signs of disease. The chief point is to examine the stools in as fresh a state as possible.

The entry of *E. histolytica* into the bowel is first effected by proliferating in the intestinal mucus. Thence they penetrate into the submucosa and produce typical flask-shaped ulcers. This process is entirely different from that of the bacillary disease.

Amoebic dysentery may give many kinds of clinical pictures. The great majority of the cases are chronic. Often they cannot be diagnosed correctly without the aid of the sigmoidoscope. The ulcers are easily seen just inside the sphincter, and *E. histolytica* can be demonstrated under the microscope in preparations from the lesions. In chronic amoebic dysentery ulcers appear like small craters, and it is known that this parasite may produce extremely minute lesions. One investigator once cut 250,000 sections of a bowel, and in one section only he found a nest of *E. histolytica* in the submucosa. There must be a great many people with these minimal lesions inside them. Many so-called carcinomata of the rectum turn out really to be instances of localized chronic amoebic ulceration.

Infections of the skin with *E. histolytica* have been known since 1892. Many instances of what is known as "synergistic gangrene" of the abdominal wall after operation are really due to cutaneous amoebiasis at the site of a colostomy. Instead of the colostomy wound healing up, the whole abdominal wall becomes gangrenous and amoebae in numbers can be found in the exudate. I recall one case of amoebic infection of the skin in a soldier who had a rectal abscess which had burst and spread, involving the whole of the lower rectum and both buttocks. He was given 8 grains of emetine; when all the sloughs cleared away and he is now perfectly well. He was an old soldier from India, who had never had "dysentery," though cysts of *E. histolytica* were present in the faeces.

Treatment of Amoebic Dysentery

In the treatment of amoebic dysentery, when the disease is acute and the amoebae are present and active in the stools and there is blood and mucus, emetine is the drug of election; but emetine is not everything that has been claimed for it. It kills off the vegetative *E. histolytica* in a strength of one in five million; but it does not entirely eradicate the disease, and it causes these organisms to scuttle away into their burrows.

The dose of emetine for an adult man is 1 grain a day, or 0.04 mg. per kilogramme of body weight. It is given for ten days and no longer. Let me beg of you not to overdo the emetine. This is a toxic drug, which may have an effect on the myocardium, and children may die of acute heart failure from overdosage. It has an affinity for the nerve endings and may produce neuritis, with muscular wasting resembling progressive muscular atrophy. In others it produces desquamation of the skin and cracked nails. It is not wise to say to one's patient, "I will give you 10 grains of emetine and you will be cured." Some people adopt the principle of giving 10 grains a month and repeating this dosage indefinitely. This is bad practice. When there are cysts in the stools you will not get rid of them with emetine therapy by the injection method, but by the oral route by emetine-bismuth-iodide, popularly known as "E.B.I." This has been shown to exert a direct action on the cysts. It is a red powder, and 1 grain is given as the first dose and 2 grains as the second. It is not necessary to use bigger doses than 2 grains. The total amount necessary to cure amoebic dysentery is about 18 to 20 grains. I have effected permanent cures with 18 grains of emetine-bismuth-iodide, and have now treated over 1,000 cases, only three of which have been known to relapse. Many of these cases have been watched for a period of ten to fifteen years.

The drug must be given last thing at night and be preceded by a sedative, the best being luminal. I usually prescribe 1 grain at 8 p.m., another 1/2 grain at 8.30 p.m., and the E.B.I. at 9.30 p.m., not allowing my patient to take anything solid by the mouth after 6.30 p.m. By this means cysts are got rid of; but that is not the whole story. It is not enough by itself to follow this regime, and it should be aided by quinoxyl (anayodin in America and chiniofon in the *British Pharmacopoeia*). These preparations are quinoline-sulphonic acid. When this substance in 2½% solution is injected into the bowel in the form of retention enema it heals up the ulcers wherever it comes into contact with them in the rectum and lower sigmoid. A preliminary wash-out of 2% sodium bicarbonate is given in the morning and then 7 oz. of the quinoline solution is run in; the patient should absorb and retain it for six or eight hours. If you give emetine-bismuth-iodide at night and quinoxyl during the day you can cure almost every case. At the end of the ten days' treatment the patient may eat any diet that he may prefer. It takes from ten to twelve days to heal the amoebic ulcers, and, if the treatment is carried out and the patient well nursed, no great inconvenience or undue risks are involved.

A great many other drugs are recommended for amoebic dysentery. Their name is legion. But I do not think any of them approach in efficacy those of which I have spoken. You can be quite certain that when the patient is once cured of his amoebic dysentery and all ulcers have disappeared, further relapses will not occur.

The Minister of Health has appointed a central technical committee to advise on the organization of mass radiography; it will be a subcommittee of the Minister's Standing Advisory Committee on Tuberculosis. Membership is as follows: Chairman, Mr. T. Lindsay (Ministry of Health), Dr. A. E. Barclay, Dr. G. Lissant Cox, Dr. J. Ferguson, Surgeon Commander W. Fitzpatrick, Dr. F. R. G. Heaf, Dr. G. Jessel, Major P. Kerley, Brigadier D. B. McGrigor, Dr. S. Cochrane Shanks, Dr. Norman F. Smith, Wing Commander R. R. Trail, Dr. Harley Williams (secretary), with representatives of the Ministry of Labour and the Department of Health for Scotland. The first sets of apparatus for mass miniature radiography are expected to be available before the end of the year, and the remainder of the 25 already ordered will be in use during 1943. The committee intends to provide a complete scheme for the full employment of these units throughout the country, including adequate technical standards. It has already considered the training of personnel and the allocation of the first sets of apparatus.

A NEW COMPOSITE MEDICAL CERTIFICATE FORM FOR FOOD

The Ministry of Food invites the attention of medical practitioners to a new and simplified form of composite medical certificate, R.G.50, which is now available on application from local food offices. This new composite certificate, it is hoped, will help to lessen the work involved for the medical profession by the schemes for priorities and extra rations. It will take the place of the three separate medical certificates which exist at present for priority milk, priority eggs, and extra soap, and also provides for possible extensions of rationing. Doctors are asked, however, for the sake of paper economy, to use up any stocks of the old forms of certificate which they may hold at the moment, before applying to the local food office for a supply of the new certificate.

R.G.50.

MINISTRY OF FOOD

MEDICAL CERTIFICATE

FOR FOOD OFFICE USE

COMMODITY	AMOUNT	PERIOD	
		FROM	TO
MILK			
NATIONAL DRIED MILK			
EGGS			
DRIED EGGS			
SOAP			

I CERTIFY THAT:—

NAME ....
(Block Letters)

ADDRESS ....

....

is:— ....

* Indicate which is applicable.

* (i) an expectant mother

* (ii) a nursing mother.

*(iii) (*a*) suffering from the condition of Class........of the Schedule of Conditions qualifying for priority supplies of MILK,

*(*b*) suffering from the condition of Class........of the Schedule of Conditions qualifying for priority supplies of EGGS;

*(*c*) suffering from the condition of Class........of the Schedule of Conditions qualifying for extra supplies of SOAP,

*(*d*) suffering from the condition of Class........of the Schedule of Conditions qualifying for extra supplies of................

and should be granted such supplies as are at present authorized.

Signed..............................Registered Medical Practitioner.
(or Certified Midwife or Health Visitor if this certificate is for category (i) or (ii) above.)

Date................

Take this certificate with your ration book to your Food Office.

The new certificate is for use in conjunction with the schedules of conditions qualifying for priority eggs, for priority milk, and for extra soap, copies of which doctors already hold. When completing the composite certificate, doctors are asked to indicate clearly under which schedule of conditions a patient qualifies. There is no period or quantity entry to make on the new certificate; that will be done in the food office. The periods and quantities which hitherto have been maxima are now standard. In cases where a patient qualifies for more than one of the commodities covered by the certificate, only one certificate form need be used, the separate entries being made in the relevant spaces.

The certificate may not yet be used in respect of national dried milk or dried eggs. Nor is paragraph (iii) (*d*) yet available for use. This paragraph is provided solely in case it becomes necessary to provide extra allowances of another commodity.

A patient aged 46 diagnosed as a case of schizophrenia had been given shock treatment with insulin in 1938, after which his mental condition became much worse. In 1940 he was treated by hpyothermia, during which a minimum rectal temperature of 80° F. was observed. During restoration of temperature external heat was applied too rapidly. Cardiovascular failure followed, and the patient died. Necropsy showed patchy bronchopneumonia, slight degeneration of the cortical cells of the brain, and a small adenoma of the pituitary gland. J. H. Talbot and his colleagues (*Arch. intern. Med.*, 1941, **68**, 1120), who report this case, believe that sudden vasodilatation was responsible for the cardiovascular breakdown, and conclude that prolonged hypothermia causes no serious changes in normal tissues.

Nova et Vetera

BOOKS OF TRAVEL BY MEDICAL AUTHORS

Contributions to fiction by medical authors—from Rabelais onwards—have often been discussed and listed. A somewhat neglected field of medical authorship—that of travel literature—is recalled and illustrated by a section of the latest catalogue of medical books issued by Messrs. Davis and Orioli, now of 1, St. Martin's Street, Wallingford, Berkshire. Quite a number of medical men, famous many years after for professional eminence, appear to have written interesting and in many cases valuable books of travel in their early days. Richard Bright, for instance, wrote an account of Vienna and Hungary, which was published in 1818. Sir John Bell's description of Italy, particularly Florence, was printed in 1825 (after his death); the first edition is represented in this catalogue. Thomas Hodgkin described his journeys in Morocco in 1863–4; Sir Henry Holland did the same in respect of Ionia, Albania, Thessaly, and Macedonia in 1812–13. Tobias Smollett wrote of France and Italy (1766), as did John Moore (1781), who described his acquaintance at Florence with Charles Edward Stuart (the Young Pretender). Martin Lister's account of Paris went through many editions (the first, 1699, is to be found in this list, as well as a later one), and was reprinted as lately as 1816. Alexander Russell, who described Aleppo, was lucky enough to include with his own writings two papers by John Hunter on the jerboa and the camel's stomach respectively; a copy of the second edition (1794) is now offered for sale. Commercially more valuable than these old travel books are some of the treasures of French Renaissance medicine now catalogued: such as Rabelais's translation of Galen, 1539, with a picture of a weird machine said to have been invented by Rabelais himself—it looks as if it may have been meant for the treatment of fracture of the patella, compound fracture of the femur, or dislocation of the hip-joint; Paulus of Aegineta (1540); Guy de Chauliac's *Surgery* (1500); and many others. Smellie's *Midwifery* (1754) is another treasure for a medical bibliophile.

Correspondence

Post-mortem Facilities for All

SIR,—Many years ago it was part of my duty, and incidentally a valuable experience, to go out to small houses to make post-mortem examinations, either in connexion with workmen's compensation cases or to satisfy the scientific spirit by endeavouring to discover the real cause of death in some obscure case where the patient had died at home after leaving hospital. It was a great convenience to many country doctors to be able to secure the services of someone, trained in the arts of the post-mortem room, who could go out with the necessary armamentarium and conduct such examinations, even though others more experienced in morbid appearances had sometimes to be relied upon to interpret the findings. There was a very great interest among the doctors concerned, and a considerable amount of interested curiosity among the people. None the less my numerous, and sometimes remarkable, experiences emphasized not only the difficulties but the unsatisfactory conditions under which the work was usually carried out, so that such an examination often proved much more of an ordeal to everyone concerned than it ought to have been if post-mortems outside hospitals were ever to become more than unusual events.

For long I have thought that this problem ought to be tackled by the public health authorities, who might make themselves responsible for having such examinations carried out by trained pathologists in fully equipped institutes. On proper request, conveyed by the medical practitioner, the public health services should be prepared to transport the body from the place of death to such an institute and, except in these abnormal times of petrol restriction, this ought to present no difficulty, whatever the distance. If desired, the body should be returned to the private residence after the examination, so that burial could be conducted in the way that was customary and acceptable to the relatives and friends. If it were generally known that by arrangement with the authorities such an examination could be made, I think the privileges would be frequently used. The practitioner should cordially welcome such an arrangement; and I feel sure that, far from any objection being raised on the side of the public, it would rather be otherwise, and in very many instances relatives would readily consent to an after-death examination which would often be the ultimate arbiter of their doubts and fears.

Naturally some confidential arrangements would have to be made as to the findings, and for some cases a very considerable amount of privacy might have to be observed. In other cases, if the identity of the subject were not disclosed, the examination could be conducted much as other examinations are made in the big pathological departments of many of our hospitals, where several necropsies take place in any one day and only those particularly concerned with the case know anything more than the mere facts of the history and the problem to be solved by the examination. I feel sure it will be generally conceded that any public health authority who undertook this work would be supplying a service which is greatly needed and which would be very much appreciated.—I am, etc.,

London. G. Grey Turner.

Lister Technique for Emergency Surgery

Sir,—As one who has endeavoured, with indifferent success, to preserve some of Lord Lister's methods, I hope that Prof. R. J. Willan's plea (Sept. 5, p. 291) may receive consideration. The need for a Listerian revival is not so great in the theatre as in the ward. The fashion of the moment seems to be to do all dressings without lotions of any sort, although, for some obscure reason, a little spirit is tolerated. The nurse who has perfunctorily scrubbed her hands with soap and water behaves as though they were surgically clean. How long the dressings from a frequently opened drum remain sterile is open to question. In a ward where most of the patients' wounds have been closed completely little harm is done, but it is not surprising that wound sepsis is reported to spread in the wards of E.M.S. hospitals. Suggestions by Mr. W. McKissock, Dr. Joyce Wright, and Prof. A. A. Miles (Sept. 13, 1941, p. 375) for coping with the problem seem to ignore the use of antiseptic lotions. Lister could open and drain a psoas abscess and avoid a mixed infection. In how many English hospitals could that be done to-day under modern methods of ward dressing?

The application of an antiseptic lotion to an open wound should be avoided, but surely it has its uses in preserving the sterility of dressings and instruments, and in cleansing the skin of the patient who is being dressed and the gloves which should be on the hands of the dresser.—I am, etc.,

Northampton. C. C. Holman.

Anaemia in X-ray Workers

Sir,—I was very glad to read Dr. F. Ellis's letter (Sept. 5, p. 291) criticizing the Ministry of Health's memorandum on anaemia in *x*-ray workers. In case anyone should think that the risks from exposure to *x* rays are negligible it would be well to recall that in the light of recent experiences in this country the Ministry of Health found it necessary to issue a warning against the setting of fractures and removing foreign bodies under the *x*-ray screen (E.M.S. Circular, 1941, Suppl. 6, Sect. III). It must be admitted that *x* rays are always essentially dangerous unless employed with adequate precautions. Clinically we know that administration of *x* rays as a bath to the whole of the body may be attended by a profound disturbance of health, which may be reflected by changes in the blood picture. Technicians are not called upon to bathe in *x* rays, but from time to time one may be guilty of negligence. I have met with examples of such. Others may sustain too much exposure from *x* rays because their hours of duty are too long or because they are working with old-fashioned or defective apparatus—conditions which are apt to exist where there is no qualified radiologist in charge.

I am in full agreement with the suggestion that far too much attention is given to the specific action of *x* rays as a cause of anaemia. In a well-conducted department anaemia is almost always due to some cause other than *x* rays, and usually responds to treatment without the affected person being taken off work. Generally variations in the blood counts are within the limits of technical error, but occasionally there are changes which are difficult to explain. Before attributing these to some specific action of *x* rays, it must be remembered that as yet we have little knowledge of the natural variations in other groups of workers working under similar conditions without contact with *x* rays. Clearly this is a problem which should be taken up by the Protection Committee in consultation with physicians and haematologists. If a definite explanation is not forthcoming at the present time, perhaps the committee will indicate certain arbitrary standards of health (as judged by haematological methods) so that we may know when a worker should be suspended from duty.

Finally, I have no doubt that all *x*-ray workers may be called upon to take a full part in national service, for under proper conditions there is no more danger to them from their work than exists in many other trades.—I am, etc.,

Oxford F. H. Kemp.

Diphtheria Immunization Campaign

Sir,—In the *Journal* of Aug. 29 (p. 255) you refer to a Press conference *re* the above in which you report the M.O.H. of the London County Council as estimating that 36% of London children are now immunized, and the president of the Home Counties branch of the Society of M.O's.H. as saying that his figures are 35% of those under 5 and 48% of those between 5 and 15, which would be about 41% of the total. I believe the latest figure given by the Ministry for the whole country is 33%. All these figures are lamentably small.

I am M.O.H. for an urban district where the figures are 75% of those under 5 and 85% of those between 5 and 15, and this is after making a quite adequate deduction for those who have been immunized under the scheme but who have by now passed the age of 15. In this district the whole of the work is left to the general practitioners, and they are paid for doing it. They provide their own prophylactics and use F.T. for those under 6, and T.A.F. for those over that age. I am also M.O.H. for a rural district where the same plan obtains. There are only two practitioners resident in the area, and therefore much of the work is done by practitioners from about ten adjacent towns. It is obviously less easy to work any scheme under these circumstances, but we have 60% of the children immunized. I am not convinced that school medical officers, school nurses, and teachers would be much help in propaganda, and as they are under the control of another authority I have not asked for their assistance. We have posted a few notices, we have had circulars distributed by the men with the scavenging lorries, and when each child reaches the age of 1 year the parents receive a letter from me reminding them that it is now time the child was immunized. I have no assistant M.O.H. and I have done no immunizations myself.—I am, etc.,

Llandudno. Arthur T. Blease.

Diphtheria Incidence

Sir,—The age incidence of diphtheria is shifting in this area. At the present time the number of adult cases (over 16 years) is relatively increased owing to a fall in the numbers of child and juvenile cases. This is the earliest clinical evidence of the success of the inoculation campaign. It is necessary to keep a sharp eye on all cases of "adult sore throat" at the present time.—I am, etc.,

Worcester. Howard E. Collier.

Breast-feeding

Sir,—We must all welcome Prof. McNeil's splendid article (Sept. 5, p. 271). One cannot help agreeing that the medical and nursing professions are largely to blame for the present unsatisfactory position with regard to the premature weaning of infants. It is so much easier to win the mother's gratitude by showing one's knowledge of the latest methods of artificial feeding than to endeavour to convince her that she ought to keep her infant on the breast. Yet, if public opinion were sounder on the question, the large majority of mothers would feed their infants as a matter of course and there would be no further trouble; it ought not to have to depend on the advice of the doctor and nurse at all.

Perhaps the time has come when we should reconsider the whole question of our treatment of the nursing mother and her baby and ask ourselves whether the present routine methods for the establishment of lactation are psychologically sound.

There is one paragraph in Prof. McNeil's "alphabet" which has occasioned these reflections: paragraph (*m*), in which he accepts the "battle between nurse and baby" in difficult cases and speaks of "goading" the child into action. On reconsideration would he not substitute "coaxing" for the latter word?

A very interesting book was written by the late Dr. Merrell Middlemore (*The Nursing Couple*, Hamish Hamilton) in which the relationship between mother and baby is analysed from the psychological standpoint. The author showed how many women are frightened of their babies, while the infants are themselves frightened by the clumsy or rough handling they receive. The mother presses her baby awkwardly against her breast while the nurse forces the nipple into his mouth; the infant is nervous, cries, tries to turn his head away, and if forced to persist soon becomes aggressive in his fear and clenches his gums, biting the nipple. The mother flinches in pain, and a vicious circle of tension and exasperation on both sides is established. Often there is definite physical distaste on the mother's part. In Dr. Middlemore's book two women are described, one of whom shuddered and said she could not watch her baby feeding, while the other kept her eyes fixed on the door of the ward as the time for the feed approached and exclaimed: "There, that's him! I can't bear to see him coming." These are extreme examples, but workers in antenatal clinics frequently meet these cases of unawakened maternal instinct where there is an obvious dislike of the idea of lactation; there is no more satisfying work than to succeed in changing the young mother's ideas by helping to awaken her fundamental instincts.

A nervous mother attended one of the Kensington welfare centres a short time ago with a small and inert baby who had refused the breast "with screams" since birth. The mother was expressing her milk, which was still abundant, and was giving it with a spoon—fortunately not in a bottle. She was anxious to feed and willing to give up all household duties to devote herself to the child. The following week she returned to the centre with pride and said that the infant was sucking well and entirely on the breast. Her revised technique had been to play with him when he wished, soothing him and encouraging him to suck at frequent intervals but not teasing him to persist. At the end of the first day she felt him beginning to suck more strongly, and subsequently he took definite feeds at half-hour intervals: their mutual adaptation was thereafter assured. At the end of the first week there was nearly two hours between the feeds, and I have no doubt that another week or two will establish the proper intervals with the infant's entire concurrence.

I should like tentatively to suggest, for the consideration of our paediatricians, that in cases of difficult feeding such as the above it may be desirable to let our rules of regular feeding at routine intervals lapse and to encourage the mother to play with her baby and give him small feeds when he wishes. This is only to establish feeding; the regular intervals will come naturally in a week or two. But the first and fundamental consideration is to get the mother to regard breast-feeding as a pleasure, and not as an irksome duty, and to establish the proper relations between the nursing couple—mutual sympathy, trust, and adjustment. It may be submitted that the routine of a hospital ward would not permit such irregularities, but might not the baby's cot be placed beside the mother's bed? One does not lay down rules for a regular life for young married couples on their honeymoon; that works itself out later. Can we not also look with more leniency upon the calls for nourishment and maternal sympathy from the new-born infant?—I am, etc.,

Kensington, W 8. VIOLET RUSSELL.

SIR,—Prof. Charles McNeil has written a very interesting and much-needed article on "breast-feeding." It is extraordinary how, at the slightest excuse, so many doctors, nurses, and mothers fight shy of making a determined effort to continue giving the baby what is by far and away the best food he can possibly have. There is one point, however, which does not seem to receive the attention it should, and this is the necessity for the mother, from the moment her baby is born, to take large quantities of fluid. For the production of milk this is much more important than taking extra solid food, although, of course, a good mixed nourishing diet is essential, and failure to take extra fluid may well result in inadequate lactation, a common cause of early weaning. It stands to reason that if the mother is to produce three-quarters to one and a half pints of fluid daily in the form of milk, in addition to her normal fluid output, then her own supplies must be kept up by drinking more herself. I have been surprised at the failure to realize this among those with whom I have discussed the point, and I am sure that if doctors and midwives insisted on their patients drinking at least one glass of water shortly before and shortly after each baby's feed, in addition to her usual fluid intake, then the percentage of those unfortunate infants who are weaned in the first few weeks of life would be lessened.
—I am, etc.,

Exeter DAVID GILMOUR.

Pyogenic Skin Infections and the Skin-carrier Rate

SIR,—The observations of Major N. H. Martin on the relation of pyogenic skin infections to the skin-carrier rate (Aug. 29, p. 245) are most interesting, but call for comment in several places.

First, he concludes that "there appears to be a significant rise in the incidence of β haemolytic streptococci on the face, but not elsewhere." The usual criterion of significance, as pointed out by Dr. Bradford Hill in his excellent elementary book on *Medical Statistics*, is that the difference between two proportions is significant when it is greater than twice the standard error of the difference. The standard error of the difference between two proportions is given by $\sqrt{\frac{pq}{n} + \frac{p_1q_1}{n_1}}$, where p, p_1, are the proportions in the two samples possessing a character; q, q_1, the proportions not possessing that character; and n, n_1, the number of observations in the series. Making the simple calculation involved, the standard error is approximately 2.69, and the difference—3.5—much less than twice the standard error. The difference, therefore, may have arisen by chance.

Second, the tabulation of the results could be altered with some improvement. I have calculated some figures not explicitly stated and find them more interesting even than appears at first sight. The carrier rate for group A is 72.8%, and of these 42.2% are carriers on all three sites selected. For the control group B the carrier rate is 44%, and of these only 15.9% carry on all three sites. These differences are undoubtedly significant in the statistical sense; but more should be known about the clinical history of both patients and controls. In how many patients had the boils burst or been opened surgically? How had they been treated up to the time of swabbing? Were the swabs taken on admission or after they had been in the ward a day or two? Were the controls ambulant healthy individuals, chosen at random, or were they ward patients suffering from some non-pyogenic disorder? If the latter, were they in the same ward as the group A patients?

This information is essential before one can assess the clinical significance of the data presented. Recent observations have shown how easily infection spreads in hospital wards, and it is common knowledge how easily boils spread when some forms of treatment are used. If the boils had been allowed to burst, or had been treated with wet applications, a high degree of skin infection would be expected; but if they were unopened at the time of swabbing and treated till then with an occlusive dressing, such a high degree of infection is unexpected.—I am, etc.,

St Albans, Herts. GEORGE DISCOMBE.

Treatment of Phosphorus Burns

SIR,—The article on "The Treatment of Phosphorus Burns" by Dr. A. Thelwall Jones (Aug. 29, p. 244) is of particular value at the present time as it provides actual clinical data regarding treatment under industrial conditions. In this article he refers to our paper under the same title (April 4, p. 433), and we think it might be useful to make the following comments:

1. Dr. Thelwall Jones states that we are in error in supposing that the object of the copper sulphate is to destroy the whole of the phosphorus, but in this we are merely following the "official" instructions, which state, "*To free the burn from*

all traces of phosphorus wash with 1% solution copper sulphate," etc. (our italics). It seems clear from both our own experience and that of Dr. Thelwall Jones that 1% copper sulphate solution can only indicate and not completely destroy appreciable quantities of phosphorus.

2. Although Dr. Thelwall Jones considers that the "official" concentrations of copper sulphate and alkali are adequate for clinical treatment of industrial phosphorus burns, he admits that they might show deficiencies under field or Service conditions, which are precisely those which our proposed treatment was designed to encounter. As an example we might quote the difficulty of removing, by means of forceps, liquid phosphorus, as compared with the usual waxy product. We might also refer to the added advantage of the osmotic effect of the concentrated applications as compared with the "official solutions."

3. We were glad to receive Dr. Thelwall Jones's support for two important points—namely: (*a*) the necessity for prolonged treatment with hypertonic "alkalis"; (*b*) the avoidance of coagulants as a continuation treatment.

It would appear, therefore, that our criticisms of the "official" method as issued by the Army authorities and the Ministry of Health receive substantial support from Dr. Thelwall Jones, and, we trust, so far as liquid phosphorus is concerned, his complete concurrence. We would emphasize that the main object of our paper was to make suggestions for an adequate first-aid treatment, which we are sure Dr. Thelwall Jones will agree is not provided by the "official" treatment.—We are, etc.,

E. W. GODDING.
The Crookes Laboratories, London, N.W.10 H. E. F. NOTTON.

"Silent" Sinusitis

SIR,—I hope that the experiences of Dr. Rosa Ford (Aug. 1, p. 128) and Dr. J. J. Craig (Aug. 22, p. 230) will not influence any of your readers to submit either themselves or any of their patients who suffer from disturbances of vision and headaches to operations on healthy nasal accessory sinuses. In the absence of clinical evidence (including proof puncture) and radiological evidence of disease it has been, and I hope still is, the custom to regard the sinuses as healthy. That a diseased sinus may be the cause of headaches is established beyond all possible doubt, but I believe sinus disease as a cause of visual disturbance to be a very rare event. As operations on the sinuses are neither easy to perform nor free from discomfort or hazard, very clear indications that the sinus or sinuses are diseased and that they are the probable cause of the symptoms are required before we submit our patients with visual symptoms or headaches to operation.—I am, etc.,

London, W.1. TERENCE CAWTHORNE.

SIR,—Further to Dr. Rosa Ford's letter (Sept. 5, p. 295) Dr. C. Newman Smith could with advantage read the chapter on orbito-ocular affections in Watson-Williams's *Chronic Nasal Sinusitis and its Relation to General Medicine*, 2nd edition, p. 117, to which are appended many relevant references. He probably has access also to the *British Journal of Ophthalmology*, March, 1936, p. 164, in which an interesting case of retrobulbar neuritis associated with sinusitis is discussed.—I am, etc.,

London, W.1. BEDFORD RUSSELL.

Sedimentation Rate and the Sedimentin Index

SIR,—I have read Dr. Della Vida's article (Sept. 5, p. 278) with great interest, but have two serious comments to make.

First, the urge to "correct" the measured phenomenon of blood sedimentation which seems to be felt in so many quarters may be founded upon a fallacy. In anaemia one of three things may happen: (1) the deficiency in cell volume may be made good, not by whole plasma, but by the watery inert vehicle (in which the solid constituents of plasma are dissolved or suspended). In this case the percentage of the plasma contents in the blood sample as a whole will remain unaltered, and therefore "correction" of the sedimentin index will be unnecessary. Or (2) the cell volume may be replaced by whole plasma. In this case the percentage of all the constituents of plasma—chlorides, sugar, urea, calcium, sedimentin, etc.—will tend to be raised. This tendency to rise on the part of sedimentin may be unchecked; in which case Dr. Vida's formula for "correction" will be absolutely accurate. But (3) the body, we know, appears to have various vigilant mechanisms for maintaining the percentages of the various blood constituents at predetermined levels, a level presumably being the balance between the rate of secretion by one organ and the rate of elimination by another. The sedimentin level may well be governed by some such mechanism.

Do we know enough about the behaviour of the sedimentin level in the blood to be able to say categorically that anaemia raises it? I have my doubts, especially as I have been able recently to determine the sedimentin indices of two patients suffering from pernicious anaemia. In one, a woman of 26 with three months' history of progressive illness and a red cell volume of 15%, showed an S.I. of 0.60 unit. The "corrected" index would be 0.38 unit, which is so incredibly low as not to make sense. The other case, a woman of 71 with ten years' history of liver-extract injections and a R.C.V. of 30%, showed an S.I. of 0.95 unit. "Corrected," this represents 0.70 unit, which again is incredibly low for a woman of that age. Personally I never dream of correcting for anaemia.

Secondly, I found, as Shuster had found earlier, that oxalated blood behaved capriciously on occasion, and for that reason I laid down in the standardized technique for determining the sedimentin index (*Lancet*, 1940, **1**, 1160) that the blood be diluted, 4 parts to 1 part of 3.8% sodium citrate in normal saline (actually I use diluted sea water); and that one unit of sedimentin was that which made this standard 80% blood mixture sediment at the rate of 10 mm. per 100 minutes. A further advantage of this dilution, which I learned to appreciate later, is that, causing bloods to sediment more slowly, it makes for more accurate observations during the process and therefore more accurate determination of maximum velocities.

Workers using oxalated bloods should be warned that they will obtain figures 25% higher than the standard unit.—I am, etc.,

Vale Royal Abbey, Hartford, Cheshire. GEORGE DAY.

SIR,—Dr. B. L. Della Vida's article (Sept. 5, p. 278) adds yet another technique which further confuses the issue of E.S.R. Any test should be as simple as possible and give the maximum of reliable information. Work to increase our present imperfect knowledge of the mechanism of E.S.R. is welcome, but over-elaboration, which only alters the magnitude of the variations while adding nothing new to our knowledge, will bring the test into disrepute.

Examination of the available evidence shows there is no method which gives any more reliable information than that obtainable from the original Westergren technique. The more one becomes acquainted with the various methods now in use the more one's respect grows for the shrewdly chosen technical data of Westergren. Our personal experience (during the last 10 years) mainly with tuberculous patients has confirmed the value of serial sedimentation tests, and made us adopt a tendency to simplification rather than over-elaboration.

Whatever ways the E.S.R. is expressed—as number, rate, or log—when compared mathematically show a close agreement. Where discrepancies occur they are within the limits of experimental error. The assumption of clinical changes from such data is unsound and quite unreliable. External factors of technique are easily controlled, but variable factors in the blood itself, due to conditions such as rheumatism, anaemia, pregnancy, syphilis, etc., and even common cold, have still to be differentiated by clinical acumen.

It is deplorable that more complicated methods have tended to replace the simple original Westergren technique. No additional reliable information has been made available than that obtained from the Westergren—preferably the second-hour reading.—We are, etc.,

PETER W. EDWARDS.
Cheshire Joint Sanatorium, Market Drayton. L. J. CUTTRILL.

SIR,—In the past one of the great merits of the erythrocyte sedimentation rate was the simplicity of the test. But there has been a tendency recently in Day's sedimentin index and the technique advocated by Dr. B. L. Della Vida (Sept. 5, p. 278) to elaborate the technique until the test takes 5 times as long per specimen, while the resulting gain in accuracy is negligible. Using the ordinary Westergren technique the time spent on each specimen after it reaches the laboratory is roughly 2 minutes, and two people can deal with 30 to 40 specimens. In estimating the maximum velocity of sedimentation one worker cannot watch more than 10 tubes, and during the 2 hours of observation he has no time to settle to any other work. Even one tube will take this time.

If the gain in accuracy over the single-reading method were striking one would have to consider adopting the M.V. method. But in a series of 350 specimens in which the second-hour reading was plotted against M.V. the correlation was very good up to M.V. 60 mm./100 minutes, and sufficiently good up to 80 mm./100 minutes. Thereafter the scatter on the graph increased, but the degree of illness of the few cases represented made slight discrepancies unimportant. The correlation between first-hour reading and M.V. is not quite so good. The Day sedimentin index, which is the log of the M.V., exaggerates small variations in the lower range of E.S.R. This is deceptive, as small day-to-day variations occur in normal subjects.

Della Vida and many other writers on blood sedimentation hold the view that temperature variations in the laboratory do not cause significant variations in E.S.R. However, a series of duplicate tests carried out last winter, when the temperature of the laboratory was from 7° F. to 10° F. below the temperature of the constant temperature chamber in which the test is always carried out at the Cheshire Joint Sanatorium, gave results in the cool specimens 10% to 20% lower than in the temperature-controlled specimens. Contrary to Day's findings, this variation was present in the M.V. as well as in the second-hour readings. This discrepancy in winter is considerably greater than the discrepancy between M.V. and second-hour reading under temperature-controlled conditions.—I am, etc.,

Market Drayton A. CLARK PENMAN.

Carotinaemia

SIR,—The article on carotinaemia by Drs. S. Almond and R. F. L. Logan (Aug. 29, p. 239) raises certain questions with regard to the metabolism of carotene. First, with regard to the transfer of carotene from mother to infant, I have confirmed—in collaboration with Dr. A. Hart (maternity department)—the findings of Menken (*Maandschr. Kindergeneesk.*, 1934, **4**, 22), Wendt (*Klin. Wschr.*, 1935, **1**, 9), Gaehtgens (ibid., 1937, **1**, 894), and Willstaedt and With (*Z. Vitaminf.*, 1939, **9**, 212) that the serum carotene in the newborn is very much lower than that of the mother (6% to 24%), although we found the vitamin A to be about equally high in both; the latter observation is in contrast with the results of those authors—except Menken (1934)—who found only traces of vitamin A in the infant's blood. In the case referred to in the article practically all the carotene must have been transferred to the infant through the breast milk. Secondly, the length of time required for pigmentation was in my experiments 20 and 16 days in the cases of one female and one male who ate 1 lb. of cooked or grated steamed carrots (with about 3% margarine) per day; the pigmentation of the face and the hands started to fade after a few days, but it persisted in the skin of the fingers for more than 16 days after carrots had been discontinued. The sclera did not show any discoloration. In three other subjects the average daily intake of 1/2 lb. of cooked carrots or the corresponding amount of spinach did not result in pigmentation after 14, 63, and 80 days. The concentrations of carotenoids in serum were in the first two cases, when pigmentation appeared, 360 and 470 γ per 100 ml. serum, while in the other three cases the level did not rise above 150 and 180 γ per 100 ml.—I am, etc.,

London Hospital, E 1. H. HOCH.

V.D. in the Forces

SIR,—In the Army considerable numbers of men are being incapacitated through venereal infection. In many cases the women who have spread the disease are known, and in some cases lists of these women have been drawn up. At the present time no effective action can be taken in inducing suspected persons to be examined, and, if necessary, treated. Under recent regulations M.O.H.s have certain powers with regard to lice-infested persons, etc. Would it not be possible for similar powers to be given in the much more serious venereal diseases? Suspected persons could be asked to go to be examined at venereal disease clinics, or to be examined by specialists privately (to be paid for under the National Venereal Disease Service), and failure to do this would involve their being kept in an infectious diseases hospital, for the purpose of isolation.—I am, etc.,

Stonehaven, Kincardineshire. H. GRANT MCPHERSON.

Operations and Workmen's Compensation

SIR,—Mr. Harold Gardiner (Aug. 29, p. 265) questions my contention as to the pitfalls which await the partially disabled worker when he is offered "light work." Perhaps he may be advised to read the *Proceedings* of the Royal Society of Medicine, May, 1942, where Mr. H. E. Griffiths, the famous surgeon and one of the pioneers of rehabilitation in this country, writes under the heading of "The Plague of Light Work": "Under the provisions of the Light Work Clauses in the Workmen's Compensation Acts before and after 1931, the employer may reduce the amount of weekly payment of compensation to the workman if he can show that the workman is fit to undertake light work and if light work is available. When the Light Work Clause first became law it was thought, or perhaps hoped, that light work would help to rehabilitate the patient. The evidence given by the British Medical Association before the Royal Commission on Workmen's Compensation has abundantly proved the opposite, and the reasons are not far to seek." Mr. Griffiths then explains: "In the majority of trades in which accidents occur there is no real light work and jobs are made by the employer for the workman at the instigation of the insurers." Is Mr. Griffiths, in the eyes of Mr. Gardiner, as "biased" as he thinks I am?

As to the other comments which Mr. Gardiner makes, I can only say that he considers too much the theoretical surface rather than the actual working of industrial accident insurance. Whether the employer's doctor is led by other than purely medical motives or not, he will always remain under the suspicion of bias on the part of the disabled. The necessity for creating medical authorities in these matters which are beyond any such suspicion is widely recognized. It is to be hoped that any new workmen's compensation law will embody the point, which of course requires fundamental organizational and administrative changes. If Mr. Gardiner thinks the present law makes it easy for the partially disabled person to claim compensation for total incapacity if he does not find a job, he does not seem to be aware that the workman must in all cases prove that he had taken *all* "reasonable" steps to get employment, a requirement which is not always easy to fulfil to the satisfaction of county courts. This makes the matter far more difficult for the worker (cf. Evidence of the Mineworkers Federation, Royal Commission on Workmen's Compensation, pp. 642 and 771). Moreover, the partially disabled worker must satisfy the county court judge that the employer who has refused to employ him has done so wholly or mainly because of the injury. As to the supply of appliances—the *Final Report on Rehabilitation*, 1939, pp. 132 and 133, states: "A considerable proportion of the cost of special appliances is, we are informed, borne by the patients themselves." The Memorandum of the T.U.C. to the Royal Commission on Workmen's Compensation stated (p. 425 of Evidence) that the omission of the workmen's compensation law to make the supply of appliances a statutory obligation had not been mitigated "to any appreciable extent" by the action of employers and their insurers.

Then comes the difficulty when a second or third employer considers employing a previously injured person. Whether he or the first employer will be liable if a second injury occurs or a recrudescence sets in, he will be anxious not to employ such men in order to avoid costly and annoying litigation. In a case which came before the Court of Appeal on June 27, 1941, it was stated by MacKinnon, L.J., that "although the county court judge found that the workman has physically recovered from his accident, yet the workman was unable to get work by reason of a disinclination on the part of the employers of that class to give him work because of the fact that he had previously had this accident, either because they thought that he was the sort of man who was inclined to have accidents or because they doubted whether the verdict of the doctors in saying he had recovered was really justified and suspected that he had not really recovered." Perhaps Mr. Gardiner will recognize that so long as such things happen one needs no particular "bias" to support very radical changes in the present workmen's compensation law, not only the reform of "weak points."—I am, etc.,

Richmond, Surrey. Hermann Levy.

The Demand on the Blood Donor

Sir,—With reference to the leading article on the above subject in your issue of Sept. 19, it should be known that, as a routine, since the outbreak of war, all donors to the Army Blood Transfusion Service have been issued, at the time of donation, with a seven-day supply of ferrous sulphate tablets, equivalent to 200 mg. of Fe a day.—I am, etc.,

L. E. H. Whitby,
Brigadier,
Consulting Physician in Transfusion
and Resuscitation to the Army.

Obituary

HEDLEY DUNCAN WRIGHT, M.D., D.Sc.

We regret to announce the death on September 9 at Mossley Hill of Prof. Hedley Duncan Wright, who had held since 1934 the post of city bacteriologist to the Liverpool Corporation and the chair of bacteriology at the University of Liverpool.

The son of Robert Stuart Wright, he was born at Ulverstone, Tasmania, on March 3, 1891, and studied at the University of Tasmania, graduating B.A. in 1910. His medical course was taken at the University of Edinburgh, where he obtained the M.B., Ch.B. degrees (with first-class honours) in 1916, the M.D. (with gold medal) in 1925, and the D.Sc. in 1927. He served with the R.A.M.C. during the last war in France, India, and Persia, and then returned to Edinburgh on his appointment as lecturer in bacteriology in the University, assistant director of the Research Laboratory of the Royal College of Physicians, and Lister Research Fellow. In 1923 he came to London to take up the post of lecturer in bacteriology at University College Hospital Medical School, and five years later the University of London appointed him Reader in Bacteriology at U.C.H. In 1930 he was elected to the chair of bacteriology at Sydney University, but returned to this country from Australia four years later to succeed Prof. J. M. Beattie at Liverpool.

Prof. Hedley Wright was for some time assistant editor of the *Journal of Pathology and Bacteriology* and published papers independently and jointly in that journal, in the *Biochemical Journal*, and in the *Edinburgh Medical Journal*. At the Annual Meeting of the British Medical Association in 1927 he was vice-president of the Section of Pathology and Bacteriology.

The death took place at Bournemouth on September 3 of Henry Dobree Woodroffe, M.D., lately of Swanage, who in his time did excellent work for the British Medical Association, which he joined thirty years ago. Dr. Woodroffe, who was a student of Trinity College, Dublin, qualified in 1907. For a number of years he had practised in the small town of Woodstock in Oxfordshire, and while there he was an active member of the Oxford Division of the B.M.A., its chairman in 1933-4, and afterwards its vice-chairman. As a member of the Arrangements Committee and in other ways he took a prominent part in the organization of the Oxford Meeting of the Association in 1936, and not a little of the success of that assembly was due to his great energy and his unusual degree of personal charm. Previously Dr. Woodroffe had practised in East Anglia—he was a representative of the very best type of country doctor—and was honorary secretary for three and a half years of the East Norfolk Division. It was as a representative of that Division that he was introduced to the central affairs of the Association, and for many years from 1924 onwards he was a familiar figure and a not infrequent speaker at the Annual Representative Meeting and the Annual Panel Conference. From 1931 to 1936 he served on the old Medico-Political Committee (now the General Practice Committee), and did good work, especially on the subcommittee which looked after the interests of ship surgeons. He was also interested in insurance practice, and for a time was chairman of the Panel Committee for the county of Oxford. Another of his interests was the British Red Cross Society, and he was a director of its organization in his locality. During the last war he served as temporary captain, R.A.M.C. While living latterly in Dorset he had acted as honorary surgeon to Swanage Cottage Hospital.

We regret to announce the sudden death at Preston, Lancs, of Dr. George Gordon Johnstone. He was born in 1887 at Ilkley, Yorkshire, the elder son of the late Thomas Johnstone, M.D., M.R.C.P. From Marlborough College, and a year at Edinburgh University, he became an exhibitioner at King's College, Cambridge, obtaining a 1st Class in Part I of the Natural Sciences Tripos, and a 2nd Class in Part II. From University College Hospital he graduated M.B., B.Ch. in 1912, M.D. in 1919, and took the D.P.H. in 1920. Johnstone served through the whole of the last war as captain, R.A.M.C.(T.F.), in charge of No. 23 Sanitary Section, being twice mentioned in dispatches and awarded the Military Cross. In 1920 he married Miss Constance Margaret Dempster of Perth. After a period as assistant county medical officer for Wiltshire, he became an assistant county medical officer for Lancashire, where he was in active work when he died. Remaining on the Reserve of the T.A. he was sadly disappointed to be classed medically unfit in Sept., 1939. Dr. Johnstone will be remembered for his sincerity, a man known well by too few, his ability and conscientious thoroughness hidden by caution and dislike of prominence. He had the gift of understanding children, among whom was much of his work. By his death the public health service of the Lancashire County Council has lost one of its most able officers. Kindly and sympathetic in manner, he was untiring in his efforts to ensure the welfare of his patients. Dr. Johnstone was a public health worker whose integrity of character and professional attainments gained the high esteem of all his colleagues and friends, and his loss will be severely felt.

Dr. Samuel McComb died suddenly at his home in Belfast on Aug. 17. He was 57 years of age and a graduate of Queen's University. In his younger days he was an outstanding athlete. In 1910 he was 100 yards champion of Ulster and Ireland, and was a member of the Cliftonville XI which won the Irish Football Cup in 1909. He served with the R.A.M.C. during the last war and attained the rank of captain. During the present war his time was largely occupied with medical boards apart from an outstanding general practice which was almost a hobby to him. Dr. McComb had a genial and lovable personality which won for him a host of friends in every walk of life, and in the profession he was universally popular. He joined the B.M.A. in 1915 and was elected chairman of the Belfast Division last year. He is survived by his widow, a daughter, and a son who is following his father in athletic achievements and into the medical profession.

The Services

Temp. Surg. Lieut. J. A. Smart, R.N.V.R., has been appointed an M.B.E. (Military Division) for skill and devoted service in the care of wounded after H.M.S. *Hermes* had been sunk by enemy air attacks in the Indian Ocean.

Temp. Surg. Lieut. W. R. D. Seymour, R.N.V.R., has been mentioned in dispatches for bravery and devotion to duty when H.M.S. *Electra* was lost.

Among the awards for gallant and distinguished services in the Middle East during the period Nov., 1941, to April, 1942, approved by the King, is the name of Major (Temp. Lieut.-Col.) Norman Berry, R.A.O.C. Major Berry, who receives the Order of the British Empire, is the only son of Prof. R. J. A. Berry, a member of the B.M.A. Council.

CASUALTIES IN THE MEDICAL SERVICES

Brief obituary notices of Group Capts. Hugh Wolfe Corner and Gerard Joseph Hanly, R.A.F., were published in this column on June 27 (p. 807) and Sept. 5 (p. 298) respectively. We are indebted to Air Marshal Sir Harold Whittingham, Director-General of Medical Services of the Royal Air Force, for the following appreciations of these two officers.

The R.A.F. Medical Service has lost two outstanding officers who joined the Service in 1924, and who served as brother officers in that year at the Central Medical Board, and later at the R.A.F. Officers' Hospital at Finchley, one having a medical bent and the other a surgical bent. They were both extremely keen on aviation, qualified as pilots in due course, and lost their lives flying on active service.

Group Capt. Corner was an able physician, and reliable and trustworthy in all his duties. In his last appointment, however, he found his true vocation, for he was a keen pilot, particularly fond of high-speed single-seater aircraft, and his devotion to flying, associated with his profound knowledge of the practical problems of aviation medicine and his friendly, helpful, and unassuming attitude to all with whom he came in contact, made him the ideal medical adviser to flying personnel. The last year of his service was his happiest year, for a unique opportunity was available for the exercise of a keen and critical mind in an environment which he loved. He was the friend of all, but particularly of the men who fly. The rare combination of high professional attainments, whole-hearted devotion to flying, and a charming and ever-youthful personality, has set a standard for his brother medical officers in the Royal Air Force which is not likely to be surpassed.

Group Capt. Hanly was an able surgeon and an efficient and zealous officer, popular with his colleagues and his staff. His interest in flying, combined with his professional qualifications, made him particularly suited to the care of R.A.F. personnel, and gave him an insight into the problems peculiar to the Service, which lent weight to his advice. The loss of Group Capt. Hanly, at a time when his matured experience was of particular value, has been greatly regretted by the Service to which he belonged.

Lieut.-Col. **DAVID LURIE**, S.A.M.C., has been killed in Egypt. He was educated at the University of Capetown, graduating M.A. with distinction and winning a Rhodes scholarship to the University of Oxford, where he took the degrees of B.M., B.Ch. in 1926. In 1932 he obtained the F.R.C.S, and shortly afterwards returned to Johannesburg, where he became registrar and, later, assistant surgeon to the General Hospital. He entered the S.A.M.C. in 1941. He was a member of the B.M.A.

Major **DOUGLAS YEOMAN RICHARDSON**, R.A.M.C., died at Moretonhampstead on Sept. 4. He was born on July 2, 1906, and qualified M.R.C.S., L.R.C.P. in 1931, taking the D.L.O. in 1939. He had held the posts of house-surgeon and out-patient assistant at the Central London Throat, Nose and Ear Hospital, aural house-surgeon at West London Hospital, and resident medical officer at the West Herts Hospital. Before entering the R.A.M.C. as temp. lieut. in February this year he was aural surgeon under the E.M.S. to Louth County Infirmary and clinical assistant to the throat, nose, and ear department of the County Hospital, Lincoln, where he had been in practice since 1935. His contributions to medical literature included "Jacksonian Attacks in Connexion with Extradural Abscess of the Frontal Lobe" (*British Medical Journal*, Dec. 15, 1934), and "A Case of Silent Mastoiditis" (Nov. 23, 1940).

Prisoners of War—War Subs. Capt. A. M. Boyd, R.A.M.C., War Subs. Capt. H. L. Clift, R.A.M.C., Lieut. T. B. D'Costa, R.A.M.C., War Subs. Capt. W. K Frewen, R.A.M.C, Capt. E. T. Gilbert, R.A.M.C., Capt. W O. James, R A.M C., Lieut.-Col. G. P. Kidd, M.C., R.A.M.C., War Subs. Capt. A. Macfarlane, R.A.M.C., Major D A. Macpherson, R.A.M.C., Major J. Parkes, R.A.M.C., War Subs. Capt. A. P. Russell, R.A.M.C., War Subs. Capt. E. T. M. Smith, R.A.M.C., Temp. Major A. McL. W. Thomson, R.A.M.C.

Wounded.—Temp. Surg. Lieut. D. V. Stott, R.N.V.R.

DEATHS IN THE SERVICES

Surg. Lieut.-Cmdr. **WILLIAM ASTLE RYAN**, R.N., died at Port of Spain, Trinidad, on Aug. 28. A native of Cahore, Co. Wexford, he was educated at the University of Dublin, where he graduated M.B., B.Ch., B.A.O. in 1932. He entered the Royal Navy as surg. lieut. soon after qualification, was promoted surg. lieut.-cmdr. in 1938, and was placed on the retired list in June, 1941.

Universities and Colleges

UNIVERSITY OF LEEDS

The following candidates have been approved at the examinations indicated:

M.D.—F. R Staub.

FINAL M.B., CH.B.—*Part II (Old Regulations)*: Mildred S Airey, T. E. Bairstow, L Crawford, C B. Dawson, Joan A Dawson, Mary D. Fox, Elspeth Harrison, E. B Harrison, Kathleen M Harrison, G. Hipps, H M. Kershaw, T G Kletz, R. E. Lawrence, G K. Laxton, D H. Lewis, Lilias J G. McLeod, H. B Peart, J Priceman, J. D Riley, P A H Rivett, Betty Sanderson, K A Simpson, R. Spink, C. Stringfellow, J W Taylor, Pauline Wynne

The West Riding Panel Practitioners' Prize has been awarded to J G. Brockis.

Medical Notes in Parliament

Tuberculosis in the Services

Mr. ERNEST BEVIN, replying on Sept. 10 to Sir Francis Fremantle, said he knew of an analysis showing that of 300 consecutive cases of pulmonary tuberculosis admitted to a certain sanatorium for the Services, it was considered that 200 could have been detected at the initial examination by mass miniature radiography as a routine procedure. Mr. Bevin said that perhaps half of these 300 cases had been examined by civilian medical boards before the adoption by these boards in Nov., 1940, of improved methods of detection of pulmonary tuberculosis. It was considered impracticable to establish mass miniature radiographic examination at medical boards throughout the country. The alternative method of detection immediately after the men had been enlisted had been found to be the most practical way of dealing with the subject.

Chairmen of Medical Boards

Mr. BEVIN, in a statement on Sept. 10, said he appointed chairmen of medical boards which examined recruits for the Forces. Appointment was normally for one year, and current appointments would expire on May 31, 1943. In making the original appointments, practitioners with special experience of work of an analogous kind were selected wherever possible. Subsequent appointments had usually been made for members of boards who had shown themselves suitable for the position. He did not know how many chairmen were retired officers in receipt of retired pay.

Mines Medical Service Proposed

On Sept. 8 Mr. J. GRIFFITHS asked the Minister of Fuel and Power what steps had been taken to establish a medical service in the several regions under the reorganization scheme, and if he would cause an investigation into the effect of diet deficiencies, particularly of fats, on the health of coal miners. Major LLOYD GEORGE said that officers of his Department, in association with those of the other Departments concerned, were working out a scheme for a mines medical service, and he hoped to be able to announce his proposals shortly. The general question of diet was a matter for the Minister of Health, but as regards coal miners the question of food in relation to the colliery canteens had been considered by the Miners' Welfare Commission in association with the Ministry of Food and in consultation with high medical authorities. He would bring Mr. Griffiths's suggestion to the Commission's notice.

Pasteurized Milk

On Sept. 20 Mr. MABANE told Mr. David Adams that considerable progress had been made towards the elimination of disease organisms from milk for human consumption by pasteurization or other methods. There was close collaboration in this matter between the Minister of Food and the Ministers of Agriculture and of Health. Pasteurization standards were set by the Minister of Health and action was taken by the appropriate officers under the Act and Regulations relating to food generally and to milk in particular. At present responsibility for distribution of milk rested upon the Minister of Food, and it was estimated that some 70% of the milk supply was pasteurized before distribution to consumers. It was anticipated that the rationalization of wholesale and retail distribution now being undertaken would result in a larger proportion of supply being pasteurized.

Diphtheria in Non-immunized Children.—Mr. ERNEST BROWN has told Mr. Leach that incomplete information at present before him, representing about 90% of the local authorities from whom he had asked for returns, showed that in the 6 months ended June 30 last, of some 13,400 children notified as suffering from diphtheria about nine-tenths had not been immunized, and that in 797 fatal cases there were 780 non-immunized children, against 17 who had been inoculated.

Notification of Scabies.—Mr. BROWN has stated that while it would not be appropriate to make scabies notifiable generally, he was prepared to consider applications from local authorities to have scabies made notifiable in their district, upon being satisfied that the authority had adequate facilities for diagnosis and treatment.

Notes in Brief

Mr. Brown has arranged with the Minister of Supply that while supplies permit rubber will be made available for the production of a strictly limited number of rubber hot-water bottles to meet the needs of hospitals and similar institutions. He has also arranged with the President of the Board of Trade for the production of a reasonable quantity of stoneware and earthenware hot-water bottles for the general public

The Ministry of Food is setting up 15 plants with a total annual capacity of about 7,500 tons of mixed dried vegetables, to be produced from 140.000 tons of fresh vegetables Distribution in the coming spring will be restricted to the Forces and certain emergency services It is intended to dry mainly potatoes, carrots, and cabbages.

No. 35

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 5.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week most infectious diseases showed a slight rise in incidence. Diphtheria had 70 more notifications than last week, acute pneumonia 27, and dysentery 21.

Measles showed the smallest weekly reduction for the past nine weeks—141. In several counties the incidence rose, especially in Yorks West Riding 94, and Warwickshire 42. The biggest drops were recorded in Durham 81, Northumberland 51, and Derby 41.

The rise in diphtheria was mainly due to the experience of the northern section of the country, the southern section showing a slight fall. No marked variation occurred in the individual counties, with the exception of Lancashire, where there was an increase of 34 cases.

Fairly large fluctuations in the trend of whooping-cough were observed, the largest increases being those of Yorks West Riding 33, and Warwickshire 19; and the largest decreases were in Surrey 32, and Essex 26.

The principal outbreaks of dysentery during the week were Surrey, Malden and Coombe M.B. 12; Oxfordshire, Oxford C.B. 15; Norfolk, Norwich C.B. 19; Lancashire, Warrington R.D. 7.

The 24 notifications of acute poliomyelitis—10 more than in the preceding week—was the largest weekly total recorded during the present year. The notifications covered 16 counties, and multiple cases occurred in Hertfordshire, Cheshunt U.D. 3; Somerset, Chard M.B. 3; Lancashire, Preston C.B. 2.

In *Scotland* 63 fewer cases of scarlet fever were notified than in the preceding week, but there was a rise in the recorded incidence of diphtheria, measles, and whooping-cough of 31, 52, and 31 cases. Glasgow held the record with a rise of 22 for diphtheria, 26 for measles, and 30 for whooping-cough.

In *Eire* the rise in the notifications of whooping-cough from 63 to 91 was due to the experience of Dublin. Five of the 10 cases of poliomyelitis were notified in Dublin.

Quarterly (Second) Return of the Registrar-General for Scotland

The birth rate was 19.3 per 1,000, the highest recorded in any quarter since 1932 and 0.3 above the average for the five preceding years. The proportion of illegitimate births was 7.3%, and was also the highest rate since 1932. Stillbirths were 37 per 1,000 of total births, this rate being 2 below the rate for the corresponding quarters of 1940-1.

An infant mortality rate of 64 per 1,000 live births was recorded—20 below that for the second quarter of 1941 and 6 below the average rate of the five preceding years. The maternal mortality was 4.0 per 1,000 live births, or 0.4 below the five-year average.

The general death rate was 13.1 per 1,000 of the population—2.1 lower than the rate for the second quarter of 1941 and 0.1 below the five-year average. There was a large reduction in the number of deaths from the principal epidemic diseases, a rate of 20 per 100,000 being recorded compared with 40 for the average of the five preceding years. Deaths from the principal causes under this heading were: influenza 61, diphtheria 58, measles 56, cerebrospinal fever 45, whooping-cough 24. The mortality from tuberculosis, 92 per 100,000 for all forms and 69 for respiratory tuberculosis, showed a slight improvement on the value for the second quarter of 1941. The former rate was 3 below, and the latter the same; but the rate for all forms was 10, and for respiratory 9, above the five-year average. The death rate from malignant disease, 170 per 100,000, also showed a slight improvement on the second quarter of 1941, but was 5 above the five-year average.

Returns for the Week Ending September 12

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,618, whooping-cough 1,074, measles 2,644, acute pneumonia 319, cerebrospinal fever 62, dysentery 146, acute poliomyelitis 20, paratyphoid 7, typhoid 30.

Medical News

The Honorary Medal of the Royal College of Surgeons of England will be presented to Viscount Nuffield on the afternoon of Wednesday, Sept. 30, at the College, in Lincoln's Inn Fields.

The Honorary Fellowship of the Royal Faculty of Physicians and Surgeons of Glasgow has been conferred on Prof. Geoffrey Jefferson, F.R.C.S., of Manchester. At the ceremony on Sept. 7 the President, Mr. Roy F. Young, spoke of the outstanding abilities of Prof. Jefferson and his international reputation in the field of neurosurgery.

Ciba, Ltd., inform us that, in the public interest, they have decided to adopt the name *nupercaine* instead of percaine and *nupercainal* for percainal, so as to avoid further confusion with the possibility of serious accidents owing to the similarity of the names percaine and procaine *B.P.* 1932, in spite of the fact that their trade mark percaine was registered in 1918.

A luncheon to celebrate the inauguration of the Queen Elizabeth Hospital for Children will be given by the president, Lord Iliffe, at the Mansion House on October 1. The amalgamated institution takes over and will maintain all endowments, named wards, departments, and cots possessed by the constituent hospitals—the Queen's Hospital for Children, Hackney Road, London, E.2, and the Princess Elizabeth of York Hospital for Children, Shadwell, London, E.1.

At a public meeting to be held under the auspices of the National Council for Mental Hygiene at 26, Portland Place, W, on Tuesday, Sept. 29, at 5 p.m., Major-General G M. Lindsay will deliver an address on "The German Psychological Machine and the Need to Combat It."

At a meeting convened by the Association of Scientific Workers to be held in the Co-operative Hall, Downing Street, Manchester, on Sunday next, Sept. 27, at 10.30 a.m., Prof. H. Levy will open a discussion on "The Place of Science in the National Effort."

Burroughs Wellcome and Co. (183, Euston Road, N.W.1) state that they are able to supply limited quantities of the alkaloid curarine for the use of research workers. Crude curare for the preparation of this alkaloid has never been plentiful, but they are now in a position to meet all reasonable demands.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Diabetic Food in Wartime

"M.A., M.B.(Cantab.)" writes: I have a diabetic patient whose glycosuria is controlled by diet, but he finds it extremely difficult to get a variety of diabetic foods, jams, etc. I should be glad if any reader could suggest substitutes or give further information.

Itching of Limbs

Surg. Rear-Admiral H. S Burniston, R.N (ret.) writes: In reply to Dr. W. A. Milligan (Aug. 15, p 208), it is almost a perfect description of what I suffered for about three months. In my case the rash was quite definitely urticarial. I therefore put it down to some error in diet and on my own eliminated various articles of food. Finally I brought it down to saccharin, and now I am content to take my tea unsweetened. The trouble is clearing up slowly, so evidently the effect of the saccharin is cumulative. The fact that the trouble in Dr. Milligan's patient has gone on for two years (about the period when sugar rationing began) rather points to my idea of the cause.

Income Tax

Absentee from Practice

C M. is an absentee from his practice. His statutory income for 1941-2 is assessed at £1,250, but his actual earnings have been £750. What relief is he entitled to, and will the position as regards income tax be materially affected if he sells the house from which he has evacuated?

⁂ In view of the fact that his actual total earnings for 1941-2 are less by more than 20% than the amount assessed, he is entitled to have the tax payable for 1941-2 assessed on his aggregate earnings for the actual year ending April 5, 1942. This position would not be materially affected by the sale of his house; it is the fact that he is entitled to some share of any receipts from the old practice, and not the ownership of the property, which matters

LETTERS, NOTES, ETC.

Codeine in Vaccinia

Lieut. H. A. Oatley, R.A.M.C., writes: As a regimental medical officer of a training battalion I am performing a large number of vaccinations (over 1,000 in the last six months), and am becoming increasingly impressed with the effect of tab. codein. co. (*N.H.F.*) in men reporting with symptoms from a successful vaccination For example, men coming in the evening with a temperature of anything up to 103° F. and feeling very ill will return next morning, after being given 2 or 3 tablets, completely apyrexial and able to continue duty, since they now admit to feeling quite recovered except for what they almost all describe as being "washed out." Before I began using this preparation I found that men (sometimes up to 5% of those vaccinated) often required up to 48 hours off duty and were sometimes sufficiently ill to merit admission to a camp reception station. Since tab. A.P.C. (*N.H.F.*) has been used as one of the standard Army preparations for vaccinia, it may well be that the value of tab. codein. co. lies in the codeine. It is because I think this apparently specific action of tab. codein co. may be of some use to other medical officers engaged in vaccination on a large scale that I am communicating this experience. Should others be able to confirm this finding it may be worth while investigating the results more scientifically than I have ventured to do, and the publication of statistics may help to establish proof of the use of this preparation in reducing the severe reaction to vaccination.

Curious Effect of a Short Circuit

Dr. J. Watson (Thornhill, Dumfries) writes: A male patient aged 86 asked me to see him. He gave a history of diarrhoea occurring only at night. During the day, apart from a feeling of weakness, he was symptom-free. This had lasted for a period of ten days The patient fortunately was in bed. On taking his pulse I noticed a tingling feeling in my fingers. This sensation was again apparent on attempting to examine the abdomen. It struck me that for some reason the patient's body was electrified. There was an all-metal bed lamp attached to the bed by a metal clamp. The bedstead was of brass. On touching the lamp and bedstead these were found to be electrified. The lamp was disconnected. This cured the short circuit. On questioning members of the household a lady-help admitted that at times she had felt a "funny" sensation in her arms when making the bed. Since removal of the bed-lamp the patient's nocturnal diarrhoea has ceased. It is interesting to note that the patient was lying on a hair mattress 6 in. thick over an ordinary spring mattress.

MEDICINE 100 YEARS AGO

Letter appearing in the *Provincial Medical Journal* of September 24, 1842, under the heading of "Medical Men and the Income Tax."

"Gentlemen,—I have read your correspondent's letter in your Number for the 3rd instant, respecting the opinion of some commissioners of taxes that medical men must not make any deductions for their horses and carriages (estimating their professional incomes), in case of their ever using them for any other purpose than that of visiting patients.

"With becoming gratitude to the said commissioners I should not think of troubling them for any advice upon the present occasion, but shall take the liberty of using my own judgment in interpreting the *spirit* of the act, and in estimating my actual professional income for the year 1841. Were I a carrier, or a brewer, I should not the less regard my horses as part of my necessary expenditure, because I occasionally used one for sending my family to church; and as I keep horses and carriages entirely for the purpose of carrying on my profession, I should not think of omitting to put them down, as items of unavoidable professional expenditure, in calculating the amount of my income. In making a distant professional journey, I might visit a friend on the way; but I should not, certainly, on that account, consider it unreasonable to deduct such travelling expenses from my annual receipts.

"The return of my professional gains for the year 1841, is an affair between me and my conscience (not commissioners). I have presumed to decide for myself what the Act requires, and have sent in such a return as I think to be a faithful one. If commissioners are dissatisfied, they may put me to my oath, and I will swear to my correctness; if my books are called for, they shall have them, and make them out how they can. I cannot, however, believe that the government will encourage the giving unnecessary trouble where no fraud can be supposed; 'frivolous and vexatious' interpretations of the Property Tax Act in the present discontented state of the country with respect to that impost, would be rather a dangerous game.

"I should like to know how far the London physicians and surgeons have complied with the commissioners' decision that they are to make no deduction for the expense of carriage and horses in their returns of income?—Yours faithfully,

A Provincial Surgeon."

WARTIME ARRANGEMENTS FOR INTERNATIONAL BIOLOGICAL STANDARDS AND THE NEW STANDARD FOR PITUITARY (POSTERIOR LOBE) PREPARATIONS

BY

Sir HENRY H. DALE, C.B.E., M.D., P.R.S.
Director of the National Institute for Medical Research, Hampstead

The International Standards for remedies of which the strength has to be measured by biological methods came into being between the two world wars, through action by the Health Organization of the League of Nations. The work was by no means limited, however, to the nations that had joined the League. Important shares in the enterprise, which began in 1921 on Dr. Madsen's initiative, were taken at the outset by experts from the countries that had not yet been admitted, and during the whole period by those from the United States of America. Even when Germany and her associates later withdrew from the League the international standards remained in use among their men of science, though without official recognition, and German industry continued to make important contributions to the materials required for the preparation of new standards.

There could be no doubt that these international standards were worth preserving for their value to research as well as to practical therapeutics, and it was clearly imperative that war should not endanger the existence of materials which embodied so much work of investigation, freely given to this common enterprise by leading experts of many nationalities. Steps were, in fact, very promptly taken by Dr. Hartley, Director of the Department of Biological Standards at the National Institute for Medical Research, to see that adequate quantities of the international standards held in that department were sent to the control centres of other countries, to meet any probable interruption of normal distribution; while the main stocks were so distributed as to minimize the risk of their destruction. When Denmark was invaded, and the further supply of the international serum standards from Copenhagen to many other countries became doubtful, the identical or exactly equivalent British serum standards were made available during the emergency, at the request of the League of Nations, wherever the need should arise. In addition to making arrangements thus to keep alive the mechanism of distribution in most parts of the world, even during the war, Dr. Hartley also deposited several complete sets of all the international standards (or, in a few cases, their exact equivalents) with institutions having the requisite facilities for ideal storage, in countries widely distant from one another. With these are deposited full technical records of the methods of preparing and using them. It can be regarded as practically certain, therefore, that when the war comes to an end these standards will be available from some source to any organization which can suitably assume responsibility for the matter in the interest of the whole world.

Meanwhile, apart from the special arrangements thus made for the standards which already existed, it was necessary to provide for the completion of work on the materials for certain new ones which were under investigation in Sept., 1939 In one such case the material was on international trial for its suitability to create an entirely new standard for vitamin E, and in due course, after agreement among as many of those concerned with the matter as could still be reached by correspondence, the international standard for vitamin E was adopted and made available (*British Medical Journal,* 1941, **2,** 553). In another case the trials, and the subsequent agreement by correspondence, were concerned with the replacement of an existing standard, the supply of which was nearing exhaustion. This was the international standard for preparations of the posterior lobe of the pituitary gland.

International Standard for Preparations of Pituitary Posterior Lobe

The history of this standard goes back to the first International Conference, held in Edinburgh in 1923, to consider the possibility of international agreement on the biological standardization of certain hormones and drugs. Among the pharmacological experts from different countries who were its members, there were few who then recognized the general importance of the principles on which Paul Ehrlich had firmly based the standardization of the antitoxic sera some thirty years earlier—the creation of a dry stable standard of reference, the definition of the unit as the activity of an exact weight of this material, and the use of samples of this central standard as a currency, enabling the weight representing the unit to be determined by comparison for any other subsidiary standard made for national or local use. In the case of the pituitary posterior lobe, indeed, Professor Carl Voegtlin, of the Public Health Laboratory in Washington, put forward in 1923, at the Edinburgh Conference, a sample of the dried acetone-extracted gland substance for consideration and co-operative trial, with a view to its adoption as a standard of a kind. The trials were successfully carried out, and the second Conference summoned to deal with such matters, which met in Geneva in 1925, readily agreed to adopt Professor Voegtlin's proposal. At a relatively late stage of its discussion this Conference also made the important decision to define a unit of activity for post-pituitary preparations as the activity of 0.5 mg. of the dried material which it had already agreed to recognize as a standard. The full record of its recommendations, however, makes it clear that it did not regard this definition as applicable only to a particular quantity of a standard material, kept at and distributed from a recognized centre. On the contrary, the evidence presented led its members to assume that any sample of this material, if prepared in accordance with the prescribed method from the perfectly fresh substance of ox pituitary glands, would have exactly the same activity; so that 0.5 mg. of any such material, wherever it was prepared, would represent 1 unit of activity. And although Professor Voegtlin was asked by the Conference to make available a small quantity of the material prepared in his own laboratory, this was to be furnished "to any authority which may require it for confirmation of its own national standard." In other words, the object was clearly to enable any national centre which had not confidence in the freshness of its raw material, or in the perfection with which it had followed the prescribed routine of preparation, to assure itself that it had in fact produced a standard of the expected optimal value. There was no suggestion that it would be proper to define the unit as corresponding to some greater or smaller weight than 0.5 mg. of such a secondary national standard if it should be found in a comparative test to be weaker or stronger than the sample provided by Professor Voegtlin's laboratory.

Experience in the administration of the international standards soon showed, however, that the basis which the Geneva Conference of 1925 had regarded as suitable for this particular case was not in fact practically applicable. A British national standard for the pituitary posterior lobe had been prepared in 1926, and had been found, indeed, by tests carried out both in London and in Washington, to be indistinguishable in activity from Professor Voegtlin's original standard preparation. Fortunately this British standard, through the co-operation given by the Armour Laboratories of Chicago in providing the material for it, had been prepared on a scale large enough to enable it to be used for a wider need than that of the national control. Applications received from all over the world soon showed that, whatever had been the intentions of the Geneva Conference, the demand for samples of an international standard for this endocrine preparation would be comparable to that for others, such as the insulin standard, for which a general distribution had been arranged. The material furnished by Professor Voegtlin being in these circumstances rapidly exhausted, it was possible to meet the situation by supplying samples of the British national standard, with a suitable guarantee of its strict equivalence to Professor Voegtlin's original sample. During this intermediate period national standard preparations were made in a number of countries and compared with the British standard. None of these other preparations was found to be more active than this, but there were a few of which the activity was perceptibly lower.

Another point of some importance has come clearly into view since the decisions made in 1925. At that date the question whether the extract of the pituitary posterior lobe owed its activities to one or to several active principles was still a matter of controversy; and the Geneva Conference had accordingly been able only to decide that the unit of activity should be regarded as contained in 0.5 mg. of the standard preparation, whether the test used for its comparative determination was based on the pressor or on the oxytocic action. By the time another Conference met in Frankfurt, in 1928, the question had been settled, as regards the artificial extract in common use, by the demonstrated possibility of making separate pressor and oxytocic extracts, each practically free from the other type of activity. It was possible, therefore, to amend the original definition in detail, and to recommend that "the activity of every such preparation should be expressed in relation to the international standard in units of pressor or oxytocic activity, and that in each case *the unit of such activity* shall be that of 0.5 mg. of the standard powder." There was no further step, however, towards the recognition of a particular preparation as the standard in question; it was still possible, by implication, to make the standard anywhere by following the prescribed routine.

By Oct., 1935, the experience which had accrued enabled the League's Permanent Commission on Biological Standardization to take the further and important step of formally accepting as the international standard preparation the British standard for the pituitary posterior lobe, which had by then been semi-officially current for international purposes for some 9 years. Since the decisions made in 1928 there had been more discussion of the possibility that the third important therapeutic application of this extract, for its antidiuretic action, might be due to yet another separable principle. This could not then (and cannot even now) be regarded as finally settled; so that the Commission at its meeting in 1935 could only provide for any possible development by authorizing the definition of a unit of antidiuretic activity, again as the activity of that type in 0.5 mg. of what was now the international standard. Unfortunately all these decisions adopting and defining the international standard and units were made, not by a conference of specialist experts, but by a Permanent Commission consisting of national representatives who left standing the implication of the earlier recommendations, according to which the standard would still serve to indicate an optimal activity rather than to fix the value of the unit and make it unalterable in either direction.

New (1940) Standard for Pituitary Posterior Lobe

It might well be suggested that such differences of conception as to the meaning and use of a standard would in this case be of theoretical rather than practical interest, since other standards had been made which were equal in potency to that being then adopted for international use, some which were weaker, but none thus far which were perceptibly stronger. And the question did not acquire practical importance until, in 1939, it became necessary to prepare a new supply of international standard material to replace in due course the one which had served for so many years in effect, and since 1935 with official recognition. With the renewed and effective co-operation of the Armour Laboratories a further quantity of the acetone-extracted and dried powder of the fresh posterior lobe substance was obtained, and was further and finally desiccated under the conditions which have now become a standard routine in the Hampstead Institute. Samples of this were distributed to expert collaborators in a number of different countries, for assay with the greatest practicable precision in comparison with the still current standard. Reports were eventually obtained from 13 different laboratories, of which 5 were in the U.S.A., 1 each in France, Holland, and Hungary, and 5 in Britain. In all, 90 determinations of the oxytocic activity of the new standard were reported from 12 of these laboratories and 38 determinations of the pressor activity from 9 laboratories; while 7 laboratories reported determinations of the antidiuretic activity involving the use of a total of more than 600 rats.

It was then at once obvious that, with very few exceptions, the results indicated a small but significantly greater activity for the new than for the current standard with respect to all the three types of activity for which the two had been compared. Two of the co-operating laboratories failed, indeed, to detect any difference in the oxytocic activities, and reported that the two standards appeared to be equivalent. All the others, however, found the new standard stronger in this respect, the highest oxytocic activity reported for it being 125% of that of the current standard. The weighted mean of the whole series of assays for oxytocic activity gave it a value of 111%. The values reported for its pressor activity varied, again, from 100 to 130%, and the weighted mean of all the determinations gave it a pressor activity of 113%. Of the 7 reports on its antidiuretic activity, 6 assigned it values between 107.5 and 122%, with a weighted mean of 116%. The seventh was quite aberrant from the others, giving a value of only 73%. It may be noted, however, that the inclusion of this aberrant finding in the calculation of the average would reduce the weighted mean of the antidiuretic values obtained for the new standard to only 112%, bringing it, in fact, into even closer correspondence with those obtained for the new standard's oxytocic and pressor activities.

By the time these results had been assembled and made available for analysis the outbreak of war had rendered it necessary to postpone, for an indefinite period, any project of an International Conference for personal discussion of their significance and of the appropriate action to be taken on them. The replacement of the current standard, however, before it had been exhausted in distribution, was becoming a matter of urgency, and it was accordingly necessary to arrive at an international agreement by correspondence. There could be no doubt that the new material was suitable for adoption as a standard, and it was further clear that the three important types of activity were represented in it in practically the same proportions to one another as in the current standard; so that the units of oxytocic, pressor, and antidiuretic activity could still be defined as the activities of one weight of the new standard. The only question to be discussed and decided was the weight of the new standard to be recognized as representing the unit in each case: should it remain at 0.5 mg., or should it be slightly diminished, in inverse proportion to the greater activity of the new standard? The following points required consideration in arriving at an agreed decision.

Points requiring Consideration

1. The decision to regard the standard material as giving to the unit an optimal rather than a fixed and arbitrary value must be considered still effective unless a new international agreement was made, for sufficient reason, to change it.

2. There were several features in the definition of the standard material which might be expected to give scope for variation in its activity. The limited experience available at the time of its adoption had not properly justified the assumption that every sample of material so defined would have precisely the same activity, wherever prepared. The material was to be the "fresh" substance of the "posterior lobes" of oxen, extracted with acetone and dried. Even if we allow that the last two procedures have end-points in complete extraction and desiccation, the interpretation given by different workers to the expressions "fresh" and "posterior lobe" could not safely be assumed to be precisely uniform. The activity of the material has, in fact, been observed to fall rapidly with increase of the interval between slaughter and the final stabilization of the dissected substance by acetone or rapid drying. Freshness in this sense, and consequently activity, may obviously vary with the efficiency of organization at the source. This might well improve during the 13 years between the preparation of the two standard materials, and any such improvement might further be accentuated by an increased use of refrigerants even during a quick transfer from abattoir to laboratory. Improved standards of dissection, again, might well give a more severe discrimination between the material to be retained as unquestionably "posterior lobe" substance and that to be rejected as more properly belonging to the stalk; while even small tags of completely inactive dura mater might easily have been included in some preparations of the material by hasty or imperfectly trained dissectors. In these different directions greater experience and perfection of procedure might easily account for the (average) additional 12% of activity shown by the new standard material.

3. The whole basis of biological standardization in units defined by fixed weights of standard preparations, since Ehrlich introduced this method for diphtheria antitoxin, has depended on the assumption that the standard itself has a practically indefinite stability. In the case of an antitoxic serum this is inevitable, since there is no independent basis of comparison and no natural upper limit to the activity of such a standard. All experience, moreover, has shown that such sera, when dried, have a high stability even in air at ordinary temperatures; so that there is no reason to suspect that a serum standard, when kept in perfectly dry nitrogen below 0° C., will suffer any appreciable loss of activity before it is due to be replaced by a fresh one.

In the case of the standard for pituitary posterior lobe the conditions are not identical with those for the sera. Even when the drying of the gland substance has been completed a measurable loss of activity occurs, sometimes in less than a year, if the dry product is kept without special precautions in air at ordinary room temperature. This would not justify an assumption that when sealed in perfectly dry nitrogen and kept at a temperature below 0° C. it would be subject to a significant loss of activity, even in many years; and the fact that none of the subsidiary standards made during its currency had proved to be stronger, while more than one had been somewhat weaker, was against the supposition that the current standard had suffered an important loss of activity during the 13 years since its preparation. Nevertheless it had to be recognized that a loss of activity of the order of 10% would be extremely difficult to detect in the absence of an independent and certainly stable basis of comparison, and that the presumption of perfect stability for this standard substance was not so overwhelmingly strong as in the case of the serum standards.

4. From the scientific point of view the maintenance of any unit of measurement without change has great importance. From the point of view of practical application, the avoidance of any possibility of a decline in the value of the unit is more important for remedies such as the pituitary posterior lobe preparations than for an antitoxic serum. With diphtheria antitoxin, for example, the effect of a small decline in the value of the unit over a decade or so—there is no reason whatever for suspecting its occurrence—would have been completely swamped in practice by the great increase, probably tenfold, in the customary dosage in units made possible in the same period by improvements and refinements of manufacture. Pituitary posterior lobe extract, on the other hand, cannot be given with a large margin of excess units to cover any possibility of a decline in unit value, since over-dosage may be as dangerous from excess of action as under-dosage from lack of effect in an emergency. In that respect its position is comparable to that of insulin.

5. Adoption of the same weight of the new standard as of the old—0.5 mg.—to represent the unit would involve an increase of the unit by not more than 15% of its *present* value. If the activity of the old standard had been constant for 13 years there would be this increase in the value of the unit as originally accepted, but it would be inappreciable in practice. It is to be noted, indeed, that several of the participants failed to detect it even in the laboratory assays made with the special care appropriate to the fixation of the unit value of a new standard. There was no risk, in any case, that such a fractional increase in value would be repeated indefinitely at successive replacements of the standard, since the complete preservation of the activity present in the perfectly fresh gland substance, as contemplated in the original definition, sets a natural upper limit; it is probable, indeed, that the slightly greater activity of the new standard represents a close approach to that limit, so that a further increase of value at later replacements is improbable. On the other hand, the possibility could not be excluded that the increase in the unit on its present value might represent a very slow deterioration of the old standard, with an average loss of about 1% of its activity in each year after its preparation; and if that were the case, a decision to fix the weight of the unit of the new standard at about 0.45 mg., to make it equivalent to 0.5 mg. of the old standard *at the replacement date*, and a continuation of this policy at successive replacements, would obviously involve the risk of a cumulative depreciation of the unit value which would eventually become of serious practical importance. It was necessary, therefore, to balance the disadvantage of a probable single increase of the value of the unit by not more than about 15% against that of a possible *succession* of depreciations of its value in the same proportion.

With all these considerations before them the participants in the preparatory investigation unanimously agreed that the weight of the new standard for the pituitary posterior lobe, representing 1 unit of activity, should be 0.5 mg., although this would entail an increase of the value of the unit of the order indicated at the time of adoption of the new standard.

Conclusion

Though such an increase in the value of the unit is not likely to be significant, or even appreciable, in practice, it will have a greater importance for the manufacturer, concerned to ensure that his product will not be found deficient if independently tested in comparison with the new standard preparation. The *British Pharmacopoeia, 1932,* in describing the assay of an extract for its oxytocic activity in comparison with the standard preparation, indicates the limit of error of the test as ±20%. It will be obvious that a product which had been passed for issue on a test made in comparison with the old standard, and which through testing error had a true activity nearly 20% below the indicated unitage, would incur a greatly increased chance of failure when compared with a standard some 15% stronger. While the existing conditions made it unusually important to avoid wasting material which, from the practical point of view, was not significantly weaker than its stated activity in units, it was also important that the small change involved in adopting the new standard should be made with the greatest practicable speed and unanimity.

Accordingly, the Hampstead Institute has issued a new Memorandum relating to the Second International Standard for Pituitary Posterior Lobe Preparations, in which the grounds for its adoption and for the redefinition of the unit, as above described, are discussed in detail. The new Standard and the Memorandum have been supplied to those countries at present accessible and to the Health Organization of the League of Nations at Geneva; and, in this country, the licensed manufacturers of pituitary (posterior lobe) extract have been notified of the changes indicated above and have been supplied with samples of the new standard preparation and the relevant Memorandum.

THE NON-TOUCH TECHNIQUE
WITH SPECIAL REFERENCE TO THE OPERATIVE TREATMENT OF SIMPLE FRACTURES

BY

H. A. T. FAIRBANK, D.S.O., M.S., F.R.C.S.
Consulting Surgeon, Hospital for Sick Children, Great Ormond Street, etc.

When Arbuthnot Lane (1894) first advocated the extended use of internal fixation in the treatment of simple fractures he insisted on a scrupulous aseptic technique. A technique founded on his original suggestions has become the routine practice of a large number of surgeons for every operation with the exception of those—e.g., abdominal operations—in which the introduction of the gloved hands into the wound is necessary. This is now known as the "non-touch technique," an essential feature of which is that a gloved finger is never allowed to come in contact with the wound or with anything introduced into it. When surgeons speak of the non-touch technique do they all mean precisely the same thing? The answer must, I think, be in the negative, particularly if the details are examined minutely. Assuming this view to be correct, it occurred to me that it might be useful to describe in detail the precautions which many surgeons consider advisable in every operation. It cannot be too strongly insisted that the scrupulous care inherent in this technique should not be regarded as called for only when a simple fracture is plated. If the precautions are accepted as advisable, even imperative, for the internal fixation of a fractured bone, they are surely advisable in every operation, with a few well-recognized exceptions.

The reason for the technique is that gloves are unreliable and cannot be guaranteed against perforation, particularly if forcible use of the hands is necessary. The technique and theatre routine described below are approximately those which, under the inspiration and guidance of Arbuthnot Lane many years ago, became the general practice of the surgeons working at the Hospital for Sick Children, Great Ormond Street. The same or a closely similar technique is now the routine practice in many other hospitals. Scrupulous attention to detail by all concerned with the operation is essential.

Theatre Routine

The skin over a *wide* area should receive a double preparation, with an interval of some hours between them, before the case is taken to the theatre. On the table the part is again painted with a solution of iodine or other preparation. The operation area is surrounded by a generous supply of sterile mackintoshes and towels, the latter being firmly clipped together and to the skin. If it is necessary to palpate the part before making the incision the skin is covered with a sterile towel or a swab consisting of several layers of gauze.

All instruments, swabs, etc., are dry: no germicide is used except that in which ligatures and suture materials are normally kept. Dissecting forceps, artery clips, retractors, and, in fact, the instruments generally, are long, so that the hands are kept well away from the wound. The theatre sister holds an instrument with forceps when passing it to the surgeon, or at any rate carefully avoids touching "the business end." All needles are threaded with the help of two pairs of forceps, and are passed to the surgeon gripped in a needle-holder. Ligatures, if used at all, are touched only with forceps and scissors and they are tied with forceps. Swabs, preferably of dry gauze, are never handled by anyone: all swabbing is done with forceps. The chief assistant is never without a pair of dissecting forceps in one hand for this purpose. Instruments used for any length of time, or forcibly, are resterilized. The knife employed for incising the skin is discarded, and a fresh knife taken for the deeper dissection. When the bleeding vessels have been secured and the wound is dry, the cut edges of the skin may be painted with iodine solution. Towels, tetra-cloths, or "veils"—call them what you will—are clipped *over* the edges of the wound, special care being taken at the extremities of the incision, to exclude the possibility of any instrument, suture, or swab coming in contact later with the raw edges of the skin. Experience shows that it is necessary to stress this point: it is the cut edge and not the surface of the skin which is the special danger. If the wound is large, towels may be used; if smaller, a sheet of close-mesh butter muslin is more convenient. I prefer specially prepared sheets of waterproof batiste between layers of muslin or gauze for this purpose. Lane insisted that the skin-edge clips should be long and heavy, so that they lie well away from the wound. For the vessels he preferred the Mayo-Ochsner type of clips, which are not only long and heavy but are powerful enough to crush the vessels and make ligatures unnecessary for any but the larger vessels. For feeling, blunt dissection, etc., a Buchanan's dissector is a most useful instrument. A needle-holder is indispensable: all sutures, including those in the skin, are tied with this and a pair of dissecting forceps.

In the open method of fracture treatment there is one, and only one, additional precaution to be taken. On a table beside the instrument table is a small sterilizer, the water in which is kept on the boil throughout the operation. All drills, screws, plates, nails, wire, etc., are left in this till required. Screw-holders, plate-holders, screw-drivers, etc., shortly before use are transferred from the instrument table to the small sterilizer, the handles projecting over the edge. After use on each occasion these instruments and the drill are returned to the sterilizer till again required. The business ends of the drill and screw-driver are returned to the boiling water after the insertion of *each* screw. In short, any non-absorbable foreign body that is to be left in the wound, and every instrument that comes in contact with these, is guarded from air-borne infection so far as is possible.

Points in Fracture Treatment

Before deciding to operate on a closed fracture that cannot be satisfactorily dealt with by other methods, the surgeon should never fail to ask himself these among other questions Is this a reasonably easy carpentering job? If I tackle it, have I a good chance of achieving something approaching anatomical perfection? Is there enough accessible bone on both sides of the fracture for the number of screws necessary to maintain the position securely? If not, can the fragments be held securely by some other device?

A few other points may be mentioned. The best period during which to operate on a simple fracture is, in my opinion, the second to the fourth day after the accident. This gives the patient time to recover from the injury, and the surgeon time to make the necessary arrangements for the operation and to have the patient's skin carefully prepared. Two assistants are necessary besides the sister in charge of the instruments. Lane insisted on a generous incision giving free access to the fragments, due regard being paid to the avoidance of damage to important structures. He stripped the periosteum from the bones, and this certainly facilitates exposure of the bone ends, the clearing of clot and muscle, and the reduction of displacement. It is questionable whether stripping the periosteum is altogether wise, and some surgeons prefer to do as little of this as possible. The subperiosteal operation gives rise to less bleeding in a *recent* fracture. Retraction of muscles is achieved with long levers, the curved ends of which are slipped beneath the bone. Lane's tapered lever with serrated edges ("rotating instrument") is useful between the fragments for sliding one on the other and overcoming shortening.

In a transverse fracture, angulation of the limb at the site of fracture till the ends of the fragments engage, followed by straightening the limb, used to be of value more often than it is in these days of orthopaedic tables with facilities for mechanical extension. Peter's lion forceps (double- and single-claw), with a screw to lock the handles, are invaluable for holding the fragments in place while the screws are inserted. When difficulty is experienced in preventing the fragments from slipping, and particularly when a third fragment of some size is present, it may be helpful to include the plate as well as the fragments in the grip of the forceps. The plate must be bent till it accurately fits the surface to which it is applied.

There must be no spring exerting a pull on the screws. Plates should, if possible, be applied to a surface of the bone that is covered by muscle, and they must be stout enough to make bending or breaking improbable. Drills must correspond to screws: soft or cancellous bone calls for smaller drills than hard bone. Lane advised that screws should pierce the distal compact bone only in young children. Particular care has to be taken that the drill-holes for the first two screws correspond with the centres of the holes in the plate, or the fragments may be slightly distracted—an undesirable though fortunately not necessarily a fatal fault. Screws should be driven home tight. The number of screws inserted in each fragment *must* be adequate for the work they have to do. For the femur, at least four screws in each fragment are necessary; for the tibia three screws; and for the radius and ulna two screws in each fragment. One of the commonest mistakes is the use of too short a plate and an insufficient number of screws. Another common fault is inadequate post-operative external splintage, or, if adequate, not maintaining this splintage long enough. These errors all lead to undue strain on the screws, which become loose, with disastrous results. It is not always remembered that with internal fixation of the fragments callus is reduced to a minimum, and in many cases no provisional callus whatsoever is formed. External splintage is necessary for a longer period, if the shaft of a bone is involved, than if a fracture is treated without operation, the apposition of the fragments being equally good in both. In the forearm the fragments may be sufficiently stable when placed in apposition to make a plate unnecessary.

The Vitallium Screw

Vitallium screws, long enough to pierce the cortex on both sides of the medullary canal, are coming into fashion, and some surgeons are showing an inclination to rely entirely on them, no splints of any kind being used. This tendency must be watched: careful judgment is necessary if disasters are to be avoided. Incidentally it is my opinion that the introduction of vitallium should not be regarded as the solution of all our troubles. Great care to guard against sepsis is still just as necessary as it was. I consider that trouble with plates and screws points to a faulty technique on the part of the surgeon. Screws become loose because they are subjected to too great a strain or because they are infected, or both. The theory of electro-chemical irritation around a steel screw is attractive but not very convincing. How do the supporters of this theory explain the by no means rare experience of finding, when removal of steel screws is called for long after their insertion, that one screw is loose while its neighbour can only be removed with the help of a screw-driver? The thread of the vitallium screws reaching this country seems to be quite unnecessarily fine: a coarser thread would, I think, be an advantage. Wires and bands around the shaft of a bone are to be avoided as a rule. Wire rarely affords adequate fixation in the shaft of a bone: disasters following the use of wire are fortunately less common than they were. Parham bands, an attractive device for an oblique fracture of a shaft which is of even diameter in the region of the fracture, are dangerous. If used at all they should be removed later. In the absence of all obvious signs of infection a circular line of absorption of the bone may occur beneath the band, and as there is no subperiosteal callus formed whatsoever, this may weaken the bone to a dangerous degree.

There are definite indications that the pendulum, which I think had swung rather too far from operative to non-operative methods of treatment for simple fractures, is swinging back towards the more extended use of internal fixation. This tendency will need careful watching, or the pendulum may again swing too far.

Finally, I venture to remind my readers that cutting down on a simple fracture is not an operation to be lightly undertaken by any surgeon. Like many another specialized operation, it is a justifiable procedure only in the hands of a surgeon with the necessary training and, above all, one whose technique is above reproach.

SURGICAL AMPUTATIONS AND THE FITTING OF ARTIFICIAL LIMBS

BY

A. W. J. CRAFT, M.R.C.S., L.R.C.P.

Limb-fitting Surgeon with the Ministry of Pensions, Queen Mary's Hospital, Roehampton

I would like first to express my indebtedness to the Ministry of Pensions, including all the surgical, medical, and technical officers, for granting facilities to make use of the data and information collected in the past 25 years, and in particular to Dr. R. Langdale-Kelham, the senior limb-fitting surgeon to the Ministry, with whom I have worked for some time and who has given me the opportunity of studying the question of fitting of limbs in detail. It is hoped the information and suggestions incorporated in this paper may be of some service to surgeons and possibly to amputees.

Amputations and Rehabilitation

Amputations have been recorded in many surgical textbooks over a number of years, particularly since the advent of aseptic surgery. The types and sites of similar amputations have varied, with the result that a difficult problem is left in many instances for those called upon to supply the prosthesis. It is stated that a good limb-maker should be able to provide a suitable prosthesis for any type of amputation, whether following a surgical operation or due to a congenital deformity. This is quite true, but it is definitely established from results of limb-fitting during the past 25 years that only certain lengths and types of stumps render the amputee free from further surgical attention. Also, latterly the artificial limb has been improved and re-designed to cause less strain and give more comfort to the wearer.

When an amputation is performed upon any limb it starts a new phase in the life of the amputee. He must rehabilitate himself, and rehabilitation is obtained only by co-operation between the patient, surgeon, and all responsible for the treatment of the stump up to and including the actual fitment of the prosthesis. There are three main objectives: first, the surgeon should provide a stump which will not require any further surgical attention; secondly, the nursing staff and others concerned should treat the stump by correct bandaging and exercises, so that it may be fitted in the shortest time with a prosthesis of a design suitable for the patient's future work; thirdly, the patient should be taught to use the prosthesis correctly to enable a speedy return to his original work or some other suitable employment, and so remove the fear of being styled a "cripple."

With the exception of Service cases from the last war it can be stated generally that surgeons have not been able to follow up and watch closely the results of amputations they have performed. Once the operation scar is healed the amputee leaves the hospital with little instruction upon the care of the stump or of the prosthesis he obtains. If the stump breaks down for any reason the amputee consults his own doctor, who may have had little experience in the treatment of such cases.

During the latter part of the war of 1914–18 the Ministry of Pensions set up an organization, with its main centre at Roehampton and 17 centres in the provinces, to provide all Service amputees with prostheses, to supervise the fitting, and to repair broken or worn parts. A very important feature was the regular inspection of the amputations, with the appropriate treatment when required. Records of this work were carefully summarized, with the result that valuable information was obtained, as I shall attempt to show.

Above-knee Amputations

Weight-bearing.—Nature has so developed the human body that, when walking, the weight is borne by the foot, and when sitting by the ischial tuberosity. If the lower limb is amputated at any level the weight ought therefore to be supported by the ischial tuberosity. About 20 years ago most amputees took the weight upon the end of the stump, but within five years over

75% of such cases were corrected. A number had to be re-amputated for surgical reasons, while others were altered before the end of the stump had deteriorated. One seldom now sees a case in which the weight is taken by the end of the stump: such amputations as the Stokes-Gritti and the transcondylar were re-amputated. This above-knee stump fits into the "socket" of the prosthesis, made of metal or wood, carefully shaped so that the ischial tuberosity rests on the inner edge, the patient thus sitting in the socket. Upon walking he naturally lifts the stump a trifle out of the socket, producing a slight "piston" action which is by no means detrimental to the stump except when the scar is terminal and adherent to the amputated end of the femur. Also there should be no scar tissue near the ischial tuberosity, the head of the great trochanter, or the upper part of the thigh, if this can be avoided.

Musculature.—The muscles of the thigh are used by an amputee to control the prosthesis in exactly the same manner as by a normal walker. The flexor muscles enable the stump to lift the prosthesis upward and forward, the lower part being swung forward at the knee-joint. The heel is then pressed on the ground and the extensor muscles push the socket backwards, extending the knee-joint and maintaining it in full extension. Diagram 1 shows the stump control of the prosthesis and the position of the scar. The adductors and abductors control the balance of the amputee on the limb as with a normal person; therefore during amputation as much as possible of these muscles should be left. With the ideal stump length, discussed later, only a small portion of the adductor magnus is removed, as shown in Diagram 2. The extensor muscles should be severed so as to end about half to one inch above the scar in order to avoid adhesion between the muscle ends and the scar tissue.

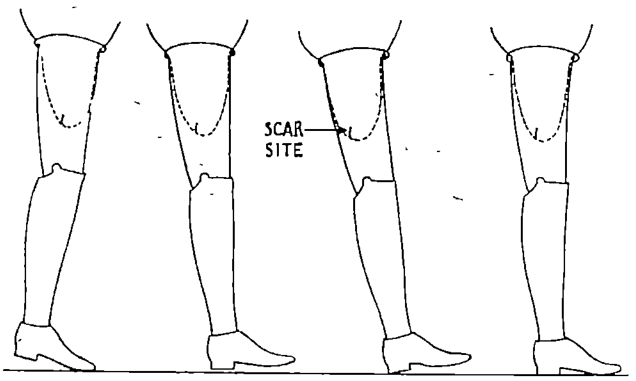

Diagram 1

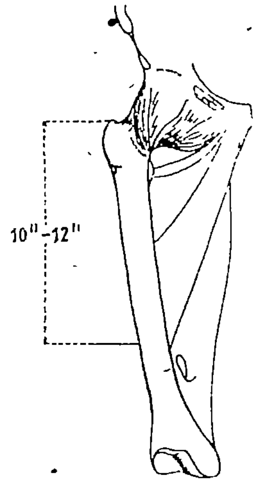

Diagram 2

Diagram 3

Stump Length.—The experience of the past 20 years and the periodic examination of stumps clearly indicate that the ideal length is between 10 in. and 12 in., as measured from the tip of the great trochanter to the amputated end of the femur. Such a length requires no further surgical treatment and affords adequate control of the prosthesis. A number of amputees with a longer stump experience circulatory troubles, while many have had to undergo re-amputation.

Scar.—With the ideal stump there is an ideal site for the scar, as depicted in Diagram 1. The larger anterior flap method ensures a transverse posterior scar about 1½ in. from the end of the stump. If complete haemostasis is obtained no drain is required and the wound will heal quickly. There are many reasons for choosing this position, the chief being that the scar will never have any direct pressure exerted upon it by the use of the prosthesis and also that there will be no traction over the scar such as would occur if it were terminal.

Flaps.—The flaps need only contain enough tissue to maintain their own nourishment; any superfluous tissue may cause discomfort in the wearing of the prosthesis.

Sciatic Nerve.—Various methods of dealing with this nerve during amputation, such as crushing, ligaturing, or injecting the end of the nerve with alcohol or similar substances, have been described in textbooks. Some of these procedures are unfortunately still in use, with the result that there is often a great deal of pain, and in numerous cases "phantom foot" is felt. The nerve should never be crushed, ligatured, or stretched. It should be treated as carefully as possible, being very delicately dissected out of the musculature and severed a little shorter than the cut muscles to prevent adhesion of the nerve-end. The artery of the nerve may in exceptional cases need tying.

Short Above-knee Stumps

If a stump has to be shorter than the ideal just described the amputation should be guided by the above principles, the chief consideration being to leave as much of the adductor musculature as possible, while at the same time removing all pathological tissue to obviate any further surgical intervention. It must be stressed that there should be no complete disarticulation of the head of the femur unless this bone or part of the joint is diseased. After amputations which leave about 4 in. of femur a special prosthesis is designed, because this short stump cannot be accommodated in the ordinary type of socket and there is no stump control. This short stump is flexed to 90 degrees from the normal position and a socket fitted half-way round the pelvis. The projection of the end of the femur, together with the natural contour of the body with the femur in position, allows the patient to wear the socket comfortably. With a complete disarticulation the socket tends to slip down and rotate on the body with every step taken. Whenever possible it is desirable to leave a part of the head of the femur for the comfort of the patient (Diagram 3).

Below-knee Amputations

With an ideal amputation and a correctly fitted limb it should not be possible to detect that a prosthesis is being worn. Examination of hundreds of cases shows that long stumps break down from circulatory disturbances, while a chronic bursitis is the result of taking the weight of the body on the head of the tibia. Modified Syme's amputations and long stumps that have taken end-bearing often call for re-amputation. The following are three important points:

1. Weight-bearing in the past has been largely taken by the head of the tibia, with a leather corset fitted round the thigh for some support. Many cases are being seen in which the resultant bursitis is too painful to allow of a continuance of this method. A longer corset is now fitted which will take the full weight on the ischial tuberosity.

2. The calf muscles should be cut away to produce a conical-shaped stump with their ends just above the resultant scar. A soft flabby stump is more uncomfortable and more difficult to fit than a thinly covered one.

3. Stump length is measured from the inner articular surface of the tibial head to the amputated end of the tibia, and all that is required is 5 to 5½ in. The fibula must be at least half an inch shorter than the tibia, otherwise bony union occurs, causing pain at the stump end or, at times, at the head of the fibula. The head of the fibula should not be removed except for pathological reasons. The front sharp edge of the amputated tibia

should be bevelled to prevent its wearing through the skin. The scar should be about 1 in. from the end of the stump on the posterior surface, formed by a large anterior flap with no superfluous tissue. This site will prevent adhesion to the bone-end. The nerve should be treated with extreme care and not be subjected to trauma by crushing or ligaturing.

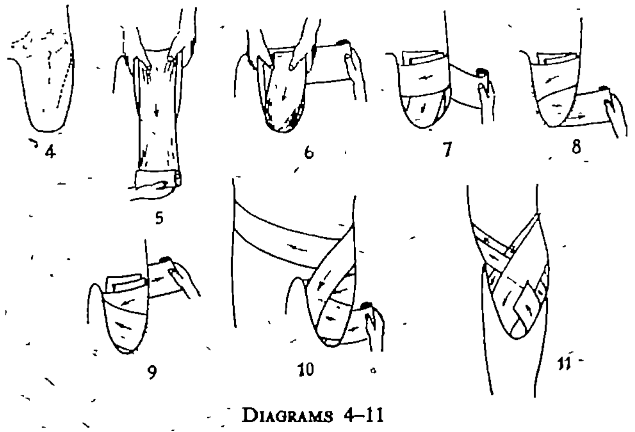
Stump Treatment

Care and treatment of the amputated limb are almost as important as the amputation itself, and should begin from the day of operation. The stump does not require a pillow or pad to rest upon, but ought to lie extended, while in the case of a below-knee amputation a back splint is often necessary to prevent flexion of the knee-joint. After the stitches have been taken out and the wound is healing, active exercises should be started while the stump is still bandaged. Movements of the joints must be encouraged, to tone up the muscles and assist in tissue reduction in the stump. Massage has been shown to be inadvisable. Furthermore, it does not reduce the oedema, but rather irritates the nerves, and should therefore not be given at any stage during recovery.

A temporary walking-leg or plaster pylon has been used in former days with the claim that it reduces terminal oedema and oedema of the stump as a whole. This pylon could not be ordered until the wound was healed and the scar consolidated, which with an above-knee amputation often took a month or more. Then the pylon was ordered and made in a week or so. The patient wore the pylon, in an effort to reduce the oedema, for a further month. I have kept careful record of measurements of stumps which had pylons fitted and of the amount of oedema reduced. In some cases the oedema actually increased; in some it remained stationary; while in a few there was a slight reduction but the patients had acquired the very distinct "pylon" swing, which was very difficult to overcome when the completed prosthesis was worn. It will be seen, therefore, that it was about 10 weeks before the artificial limb could be ordered. The pylon is now only used in special cases.

The modern method devised by the Ministry of Pensions and adopted by the E.M.S. is to bandage the stump with crêpe bandages from the time the stitches are taken out. It has been proved from records compiled at Roehampton that an above-knee stump requires only three weeks' bandaging to render it fit for measurements to be taken for an artificial limb. Thus with this above-knee site actual limb-fitting can take place in less than 8 weeks from the day of amputation, resulting in a great saving of time and expense, and the earlier return of the amputee to work.

In bandaging above-knee stumps it is imperative to use crêpe bandages 6 inches wide. At present they are not made long enough, so that two have to be sewn together. The bandage must be wound tightly and evenly, otherwise the necessary firm application to the stump cannot be obtained (Diagrams 4–11).



DIAGRAMS 4–11

The end of the bandage must be applied to the upper front surface of the stump and be held securely by the patient's thumbs. It is then passed down the front of the stump, back over the end, pulled tightly with even pressure to the upper part of the posterior surface of the stump, and held by the patient's fingers. This process is repeated by bringing the bandage down the back of the stump, over the end to the starting-point—still being held by the patient's thumbs—and drawn down over the end to the back of the stump.

The patient must not allow the tension to slacken in the bandage, which thus supports the tissues in the end of the stump. The bandage is next applied round the upper part of the stump to hold the first applications, and firmly enough to allow the patient to remove his hands. It is brought round the end of the stump very tightly so as to compress the tissues, but not too tightly round the upper part. If the bandage was finished off in this manner it would tend to slip down and off the stump when the patent walked about. To prevent this it is applied round the waist as shown in Diagram 10, and finally round the stump (Diagram 11). Particular care should be taken that the crossing of the bandage on itself when applied round the waist occurs at the side of the body and not on the front, otherwise there will be a tendency to flex the stump. This bandage should be reapplied three or four times a day to take up the new shape which results from reduction of the oedema. Figures are available which show that stumps treated in this way have uniformly shrunk 2 in. in circumference in less than 14 days, thus rendering limb-fitting possible.

The application of a 4-in. bandage to an above-knee stump is useless. Furthermore, the method of applying a crêpe bandage tightly at the upper part of the stump and bandaging downwards will retard the reduction of oedema because it imposes a constriction on the upper part.

To treat a below-knee stump a 4-in. crêpe bandage is applied as in the above-knee method. Three slings are used to support the oedematous tissue, and the bandage is applied tightly and firmly around the end. The bandage is taken above the knee to prevent it slipping off the stump, but the front of the knee over the patella is left free so as to afford mobility to the knee-joint.

Stump Exercises.—A recent development in the care of stumps after amputation is a course of exercises adopted to re-educate the remaining muscles of the stump and thus prepare it to control the artificial limb. A narrow sleeve, about 4 in. wide at the back and 2 in. at the front, from which a cord passes over a pulley and suspends a weight of 7 to 14 lb., is placed on the stump as shown in Diagram 12A. The stump is extended against the pull of the suspended weight to assist the musculature in regaining its strength—the weights, rate of exercise, and duration varying with the increase in muscle tone. The adductors are similarly exercised by the patient's standing with his side toward the pulley, the stump being drawn towards the midline of the body. If the patient is at home the exercise can be carried out by allowing the cord to pass over the back of a chair upon which somebody is sitting to steady it (Diagram 12B).

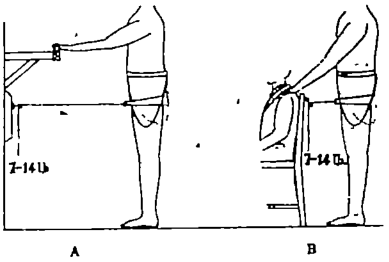


DIAGRAM 12

Arm Amputations

Arm stumps are not weight-bearing, and are subject to quite different strains and stresses from those of the lower limb. Long arm stumps are not so liable to circulatory disturbance, except the very long ones which are produced by disarticulation through the wrist and elbow. The ideal length of an upper-arm amputation in an adult is 8 to 9 in., measured from the tip of the acromion process to the amputated end of the humerus. If the stump has of necessity to be made shorter, at least half an inch of humerus should be left below the axillary fold, thus enabling good control to be maintained over the artificial arm.

If a still smaller length has to be fashioned, every endeavour should be made to leave some part of the head of the humerus. The scar should not be on the anterior or posterior aspect of the stump because pressure is exerted on these surfaces in using the arm. A terminal scar from equal anterior and posterior flaps is ideal, with again little tissue in the flaps and a conical stump. Adhesions of the musculature to the end of the humerus must be avoided. This latter consideration is the chief objection to guillotine operations, which are otherwise satisfactory.

The length of the lower-arm amputation is measured from the tip of the olecranon to the amputated end of the ulna, and should be about 7 in. with the elbow flexed. The radius should be at least half an inch shorter than the ulna to obviate cross-union, and a conical stump be produced for the comfort of the patient and to permit him to use the prosthesis. The scar should be terminal in a line across the ends of the bones, and the flaps should contain no superfluous tissue. The nerves must be cut across cleanly to avoid the "phantom hand."

If an amputation has to be carried out with a shorter length than that suggested above, it will not prevent the amputee from using an artificial arm if at least three and a half inches is allowed to remain, but in such a case more muscle tissue must be trimmed away and a real bony stump left. If as a result of an accident, disunited fracture, or other cause a surgeon is confronted with a disarticulation of the elbow- or wrist-joint, an ideal site amputation is preferable, because these disarticulations do break down repeatedly. Furthermore, artificial arms must have a rotary mechanism at the wrist, and an above-elbow prosthesis will have the elbow-joint together with a rotary arm mechanism. These points are often forgotten when disarticulation amputations are performed.

In all arm amputations the patient should be encouraged to use the proximal joints and truncated muscles as early as possible. Crêpe bandaging with 3-in. bandages is used when the stitches are removed. An arm amputee usually has a more despondent outlook than a leg case. It is for this reason that such cases should be fitted with prostheses as quickly as possible, otherwise there is a tendency to rely too much on the remaining hand. An arm can in the average case be fitted and used within a month of the operation.

Amputations of parts of the hands which have suffered trauma are indeed difficult. If any two working digits, or the thumb or part of it with a digit, can be saved it should be done to form the basis of a working hand. It is, however, surprising what appliances can be fitted to mutilated hands which may have only the minimum of a digit.

Amputations in Children

Children may have a limb amputated as a result of trauma, bone disease, congenital deformation, or aerial bombardment. These cases should all be treated early, for a child will quickly learn to use a leg or an arm with great ability. A plaster pylon or peg-leg should not be advised for the use of a child.

Summary

Records compiled by the Ministry of Pensions during the past 25 years definitely show that periodic examinations of amputated stumps are desirable.

The most suitable and trouble-free lengths of stumps, the position of the resultant scar from correctly fashioned skin flaps, and the treatment of the severed nerve are indicated.

In the past, stumps have received but little supervised attention with regard to their preparation for the fitting of a prosthesis.

A new method of crêpe bandaging is now used, the results of which prove its efficacy in reducing the oedema in a much shorter time than by previous methods. Pylons are not necessary, generally speaking. A course of exercises assists in preparing the stump musculature to control the artificial limb.

Arm amputations, not being weight-bearing, necessitate a different position for the scar. The stumps require bandaging and exercises to encourage the greatest range of joint mobility. The artificial arm should be fitted as soon as possible.

Children should not be fitted with non-articulated peg-legs. They should have a prosthesis at an early age, whether they be arm or leg cases.

RENAL IMPAIRMENT DUE TO CRUSHING LIMBS IN ANAESTHETIZED DOGS

BY

M. GRACE EGGLETON, D.Sc., M.R.C.S.

K. C. RICHARDSON, M.Sc.

H. O. SCHILD, M.D., Ph.D.

AND

F. R. WINTON, M.A., M.D., D.Sc.

Impairment of renal function in dogs under nembutal anaesthesia ensues immediately after a period of 4 to 5 hours, during which both hind limbs have been tightly bound with rubber tubing from ankle to hip and the thigh muscles compressed in a vice and hammered for a few minutes. Removal of the bandage is followed by a large fall in arterial pressure, and by either anuria or severe oliguria. In the latter event the urine is deeply pigmented, presumably with myohaemoglobin, which is freely excreted by the normal kidney, and the creatinine clearance is very low, which might be attributed in part to the low arterial pressure. Restoration of the arterial pressure with intravenous gum-saline or ox serum usually initiates or increases the urine flow; but even if the flow is raised to its initial value with diuretics the creatinine clearance, and therefore the concentrating power of the kidney, recovers to only about one-quarter of its original value.

The low arterial pressure following release of the limbs is not responsible *per se* for the damage to the kidney, since maintenance of even a lower blood pressure for an hour by means of a histamine infusion does not involve reduction in creatinine clearance during a subsequent period at normal arterial pressure. The reduction in urine flow after release of the limbs does not in itself account for the renal damage, since prevention of this reduction by diuretics does not materially affect the degree of the ultimate damage.

The damaged kidneys respond to large doses of diuretics with large increases in urine flow but only small increases in creatinine clearance, which may reach about one-half the normal value. In these respects we did not detect a significant difference in the efficacy of intravenous administration of hypertonic sodium chloride, isotonic sodium chloride, sodium bicarbonate, or sodium sulphate. The depth of colour of the urine from damaged kidneys was not consistently related to the severity of the damage as indicated by fall in creatinine clearance. The nature of the pigment was not examined in this series of experiments. Dr. Rimington has, however, identified the pigment in urine secreted under similar conditions in a later series as mainly myohaemoglobin.

Post mortem there was extensive injury to and oedema of thigh muscles, but no fracture of bones. The kidneys showed a brown cortex and a distinctively bluish-pink medulla, often with a narrow light-coloured zone between the two. The kidneys were notably flaccid, in contrast with the tense kidneys normally found after experimental poisoning.

Microscopically, the kidneys were characterized by the presence of material within the lumina of the tubules which might have been capable of blocking some of the tubules. The material was particularly concentrated in the terminal portion of the proximal convoluted tubules. The distal and collecting tubules were usually free and distended. There was, however, no consistent relation between the extent of the deposit and the impairment of renal function; and, indeed, extensive deposit occurred in some kidneys which were functionally undamaged. In the only dog in which the anuria could not be antagonized even by huge doses of diuretics there were mitochondrial changes in the proximal tubule cells, indicating the action of a poisoning agent.

Discussion

In these observations on 21 dogs we used the reduction in creatinine clearance as the chief indicator of renal damage because, like the inulin clearance, it is probably a measure of the glomerular filtration rate in the dog unless there is leakage of creatinine from the concentrated urine in the tubules back into the blood. The renal damage described above is probably not due mainly to *reduction in glomerular filtration rate,* because oliguria from this cause is associated with very high creatinine and low chloride concentration in the urine, whereas in these experiments the creatinine concentrations are low and the chlorides may be increased. Microscopically the damaged organ appears fairly vascular.

Blockage of the tubules, suggested as a possible factor by the appearance of the deposit in them, should produce a tense kidney, in contrast with the striking flaccidity observed in these damaged kidneys. The deposit does not appear compact enough, nor does it occur in a sufficiently high proportion of tubules, to lead one to expect that it could reduce the creatinine output to one-quarter. A more likely hypothesis would involve release of a *poison* from the damaged limbs that affects the *tubule cells* by increasing their permeability to creatinine, urea, and other substances which are concentrated by the kidney. These substances would diffuse from the concentrated solution in the distal parts of the tubules across the tubule walls to the blood in the venules. Hastening the flow of liquid down the tubules with diuretics should reduce the loss by leakage of creatinine and so increase the creatinine clearance, an expectation which accords with observation. The main objection to regarding this as a self-sufficient hypothesis. is that poisons such as cyanide or mercury salts produce an increased urine flow, due to inhibition of water reabsorption, before they produce the anuria due to increased permeability. Correspondingly, organs poisoned in this way are usually tense. This is, however, not an insuperable objection to the view that the poison here in question affects the permeability mainly.

Such a poison might reach the tubule cells either from the blood stream or, if diffusible, from the lumen of the tubule. In the latter event the poison itself might well be a substance which is concentrated in the tubules, and act the more potently in virtue of its concentration. This possibility has, however, been excluded in the following way. Partial obstruction of one kidney by an increase of ureter pressure resulted in a fourfold concentration of urine (as evidenced by creatinine-U/P ratio) compared with the unobstructed side. If the toxic agent released from the limbs had been similarly more concentrated on the obstructed side the severity of the damage should have been greater on that side. In fact, the obstructed side, after removal of the obstruction, was, if anything, a little less severely damaged than the unobstructed side.

So far as available evidence goes, the injury to the kidneys in our series of dogs appears to be of the same kind as that in man after comparable prolonged crush injury to the limbs. The essential nature of the renal damage has not yet been determined, but the evidence suggests that the main factor may be concerned with increase in permeability of the renal tubules due to a toxic agent released from the damaged limbs, while there may be an additional factor involving reduction in the rate of glomerular filtration probably due to lowering of glomerular capillary pressure.

VARIATIONS IN THE RESPIRATORY RHYTHM OF PROGNOSTIC SIGNIFICANCE IN MALIGNANT HYPERTENSION

BY

H. O. GUNEWARDENE, M.B., B.S., D.M.R.E.
Radiologist, General Hospital, Colombo

Recently I drew attention to variations in the respiratory rhythm in a case of malignant hypertension in its terminal stages (Gunewardene, 1938). A similar type of respiration has been noticed in cases of meningitis (Hutchison and Hunter, 1929). The characteristic feature is that the respirations are grouped; in each group the initial excursion in the tracing is the largest, the subsequent ones getting smaller, until the movements cease for a moment. This means that the depth of the respiration gradually declines as in the waning phase of Cheyne-Stokes respiration. In that case, however, there was no period of apnoea.

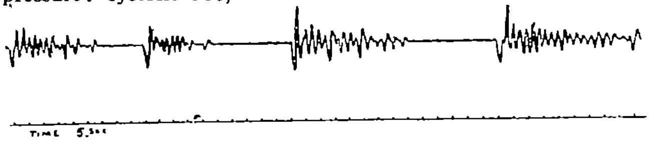
This type of respiration is seen in the terminal stage of malignant hypertension when pronounced albuminuria, persistent hypertension, and extensive eye changes (haemorrhages, exudates, cotton-wool patches, oedema of the disks, etc.) are present. The patient is generally quiet and lies flat on the back without a suggestion of the breathlessness of the cardiac type which previously had been well marked. A little restlessness, not continuous, is often observed; he opens his mouth frequently and breathes as though he is yawning half-heartedly. Occasionally he is irrational. Sometimes there is maniacal excitement; at other times a little drowsiness suggestive of a uraemic state. Uraemic twitching or convulsions were not observed.

These variations in the respiratory rhythm in association with malignant hypertension have not been described before, so far as I can gather from the literature available in Ceylon. Their cause has yet to be explained. Are they due to cerebral oedema, or to the effects of toxins on the respiratory centre? Is the alteration in the chemistry of the blood responsible for them? Eyster has shown that Cheyne-Stokes breathing can be produced in dogs by a rise and fall of the blood pressure in the presence of raised intracranial pressure.

In the following case, grouping of respiratory movements similar to those in the case referred to above was noticed, but each group was followed by a period of apnoea. The tracing is unlike Biot's type, but resembles that of Cheyne-Stokes respiration with the waxing phase absent. The rhythm is irregular and the depth of the respirations varies.

Case Report

The patient, a male sedentary clerical worker aged 42, was admitted on March 7, 1939, complaining of occasional occipital headache, giddiness on and off, and blurring of vision. He was lying quiet, but a few days previously he had been very dyspnoeic. Examination revealed the following characteristics. Heart: heaving apex beat—in fifth space, midclavicular line: second aortic + + ; no murmurs. The lungs were clear. Blood pressure: systolic 300, diastolic 180. The brachial and radial arteries did not feel much thickened, nor did palpation suggest such high pressure. Pulse 78, regular. Urine: scanty; S.G. 1010; albumin 0.7%; no sugar. Fundi showed oedema of the disks; flame-shaped haemorrhages, exudates, thickened arteries, very congested veins. Blood urea, 224 mg. per 100 c.cm.; urea clearance, mean 7.26% normal.



Treatment consisted of venesection; administration of sodium nitrite, theominal, etc.

During his stay in hospital the blood pressure varied between 210/140 and 260/170 (not eliminating effects of drugs). He became somewhat irrational, yawned half-heartedly, and later became a little drowsy and quiet Just before his death (under ayurvedic treatment) on April 7, 1939, he complained that he "couldn't breathe." The accompanying illustration shows the respiratory tracing (thoracic) of this case.

According to Harrison (1939), the carbon dioxide tension in malignant hypertension is abnormally low and patients with periodic breathing have arterial blood which is under-ventilated as regards oxygen and over-ventilated as regards carbon dioxide. It has also been shown that the administration of carbon dioxide abolishes periodic breathing. The fairly sudden transition of a dyspnoeic, sometimes orthopnoeic, patient into a condition of tranquillity would suggest that changes in the chemical constituents of the blood gases and the tissue fluids play a significant part in the production of periodic breathing and the cessation of dyspnoea.

Summary

A form of variation in the respiratory rhythm associated with malignant hypertension is described.

There are changes in the periodicity as well as the depth of the respiratory movements.

These changes are of grave prognostic significance even when the patient does not look seriously ill, the duration of life in the cases described being not more than 6 weeks after their onset.

I gratefully acknowledge the co-operation of Dr. J. R. Blaze and Dr. Cyril F. Fernando, under whose care the patient was; also the kind services of the Physiological Department, Ceylon Medical College.

VACCINATION IN GLASGOW DOCKS

BY

GEORGE BUCHANAN, L.R.C.P., L.R.C.S. D.P.H., D.P.A.
Medical Officer, Clyde Navigation Trust

AND

STUART LAIDLAW, M.D., B.Sc., D.P.H., D.P.A.
Senior Assistant Medical Officer of Health, Glasgow

The following is an account of an investigation into the potency of vaccine lymph and the effect of vaccination on the sickness and industrial accident rates among Glasgow dock workers.

As a result of small-pox of a severe type occurring in Glasgow, the medical officer of health, on June 29, 1942, issued an appeal for mass vaccination of the city's population. Since the disease had presumably entered through the Port it was felt that every endeavour should be made to have dock workers vaccinated at once. At all times close co-operation is maintained between the city's health services and the Port Authority (Clyde Navigation Trust), so that the drawing-up and completion of the scheme here outlined naturally fell to be dealt with by us. The scheme was approved by the medical officer of health, the Clyde Navigation Trust, and the port regional director.

Outline of Scheme

The first essential was to carry out vaccination promptly and with the minimum interference with the normal working of the harbour; secondly came the necessity of informing the dock workers of the need for vaccination; and, thirdly, conveniently situated vaccination centres had to be established in the Docks.

It was decided to utilize the existing gas-cleansing stations in each dock as vaccination centres and, on the day before the opening of the centres, to make use of a broadcasting van to explain the need for vaccination and to announce the time and place for workers to attend. This scheme answered extremely well, and over 60% of the workers in the Port of Glasgow availed themselves of the opportunity. The medical and nursing staff employed were directed to pay particular attention to the technique of vaccination as outlined by Sir Alexander Macgregor in his communication.

Result of Vaccination

Of the lymph used 95% was supplied by the Government Lymph Establishment, the remaining 5% being from other manufacturers. Our impression was that the Government lymph was somewhat more potent, although all the other varieties gave satisfactory reactions. The follow-up of many of the workers was far from easy owing to the constant changes of working shifts and the movement of gangs of dockers from one dock to another as ships arrived and departed, and we, of necessity, had to satisfy ourselves with records of 1,000 out of the total vaccinated. The accompanying table shows under four headings the results we obtained. (A) Severe reaction evidenced by constitutional upset, enlarged axillary glands, fairly extensive localized reaction, with inflammation extending from the pock sometimes up to the shoulder and down to the forearm. (B) A normal vaccination pock with little or no constitutional upset. (C) An immune reaction sometimes described as the papule of immunity of Pirquet. (D) No reaction.

Table showing Results in 1,000 Cases

	A (Severe)	B (Normal)	C (Immune)	D (No Reaction)
No. of cases	121	719	102	58
Percentage	12	72	10	6

From the table it is evident that the lymph used was particularly potent, 84% of the cases showing severe or normal vaccinations and a further 10% an immune reaction due in practically every instance to a previous successful vaccination. The 58 cases which showed no reaction were all revaccinated, when only two showed an immune reaction.

Effects on Industry

We feared that mass vaccination would interfere with the normal work in the harbour and thus slow down the national effort, but this has not been so. In fact, less than 3% of all classes of workers were off work on account of vaccination. The maximum period of incapacity was one week, the great majority being back at work within 48 hours. Scrutiny of the sickness rate among dockers, office staff, and Clyde Trust employees for the 28 days subsequent to vaccination showed no increase over the normal rate prevailing at this time of year.

The industrial accident rate has also shown no increase above the normal, despite the fact that many crane drivers, capstanmen, and winchmen were vaccinated successfully, and were plucky enough to continue at work despite very sore arms.

Comments

A good previous vaccination scar was no guarantee of immunity. For example, one female who had five large foveated scars resulting from vaccination in infancy, and subsequently in 1921, had a very severe reaction.

Stout persons generally had much more severe local reactions than thin persons.

Elderly persons often showed severe reactions even although previously vaccinated.

Many suffered from a coryza, sometimes associated with sore throat, of about three days' duration from the 8th to the 11th day after vaccination. In no case was the coryza severe enough to cause incapacity for work.

Women reacted more severely than men in the same age groups.

We found that vaccination of the lower limbs caused much more discomfort than vaccination of the upper limbs.

Nine cases in our series showed a post-vaccinial rash; four of these were urticarial in type and associated with previous acne or scabies, three morbilliform, and two scarlatiniform. They all occurred between the 9th and the 10th day following vaccination and disappeared within 48 hours. We noted no case of papular urticaria, nor did any of the dock workers develop pustular rashes resembling small-pox. Neither did we see any case of post-vaccinial encephalitis nor any person who developed nervous symptoms following vaccination. Several cases showed a somewhat delayed local reaction to vaccination.

This investigation was made possible only by the willing co-operation of all classes of dock workers, and we wish to thank the medical officer of health, the general manager of the Clyde Navigation Trust, and the port regional director for permission to print this short review.

The Chadwick Trustees have arranged for the following public lectures to be given on Tuesdays at 2.30 p.m.: Oct. 6, at Royal Society of Tropical Medicine, 26, Portland Place, W., Sir Leonard Hill, F.R.S., "The Interrelation of Clothing and Shortage of Fuel in Matters of Health"; Oct. 27, at Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., Mr. W. T. Creswell, K.C., "The Forensic Aspects of Wartime Public Health Legislation"; Nov. 10, at London School of Hygiene and Tropical Medicine, Keppel Street, W.C., Bossom Lecture by Miss Jocelyn Adburgham, "Land Settlement—Its Sanitary and Architectural Aspects and After-war Possibilities"; Nov. 24, at Westminster Hospital Medical School, Horseferry Road, S.W., Malcolm Morris Memorial Lecture by Sir Arthur MacNalty, "The Prevention of Tuberculosis in Peace and War"; Dec. 8, at Royal Society of Tropical Medicine, Dr. W. Norwood East, "The Differentiation, Prevention, and Treatment of Anti-social Behaviour Disorders." Admission to the lectures is free, and further particulars can be had from the secretary, Chadwick Trust, 204, Abbey House, Westminster, S.W.1.

Medical Memoranda

A Case of Adder Bite

Publication of the following history of a case of adder bite that we have treated recently is prompted by the query of Dr. C. W. Walker in the *Journal* of July 25 (p. 118).

CASE REPORT

A well-developed woman, aged 63 and weighing about 12 st., was bitten by an adder on June 30 while picking wild flowers on the roadside. Two punctures were made by the fangs on the dorsal surface of the web between the middle and ring fingers of the right hand. The bite was inflicted at 5 p.m., and a tight constriction was applied to the wrist about 7 minutes later.

When first seen by one of us (D. S.-J.) 20 minutes after the accident the patient was rather faint (probably from psychic shock) and the hand was swollen as far as the constricted wrist. The two small punctured wounds were incised to provide escape of toxin, and, after a few ounces of fluid (principally blood) had escaped, the constriction at the wrist was removed. Five hours later the whole arm was swollen and very painful.

By the following morning there was marked toxic cellulitis the whole way up the arm, extending to the shoulder and neck on the same side. The oedema of the loose tissues at the base of the neck was so pronounced as to suggest the presence of free fluid. Forty-eight hours after the bite the oedema had increased both in extent and in degree, the back of the hand was very puffed, and the patient was unable to flex her fingers. There was, however, no local reaction at the site of the punctures. The path of the lymphatics from wrist to shoulder was indicated by a series of wide areas of capillary haemorrhages into the subcutaneous tissues, the intervening areas in some cases seeming in comparison so white as to appear blanched.

Four days after the bite the oedema, though less in degree, had spread to the scapular region and upwards into the right side of the scalp. Slow improvement followed from now onwards, the patient being under treatment for 4 weeks. At the end of this time almost full recovery had taken place. All oedema had disappeared, but the muscles of the forearm were still a little thickened and the right side of the neck felt somewhat stiff. Constitutional symptoms were never very prominent, the temperature being 99° on the second and third days and normal from the fourth day onward.

In the absence of specific antivenene the treatment was merely palliative. At the outset coramine was given to combat shock, and sulphapyridine as a prophylactic. On the morning of the second, third, and fourth days the patient received 1 c.cm. of "S.U.P. 36" as a detoxicant. On the fifth and sixth days mersalyl was administered to relieve the oedema by promoting diuresis. In addition the whole limb was immersed frequently in warm iodine baths.

COMMENT

Snake venoms contain two principal types of toxins—namely, neurotoxins and haemotoxins. Neurotoxins preponderate in venoms from cobras and mambas, while haemotoxins are found in the adders (vipers) of the Old World and in the rattlesnakes of the New World. Neurotoxin may kill rapidly by paralysis both of the medullary centres and of the peripheral nerves, sensory and motor, in the last action resembling curare. Survival is usually followed by full recovery without sequelae.

Haemotoxic venom damages by enzyme action the capillary walls, the lipoid membranes of the blood corpuscles, and the tissues themselves, resulting in extravasations of blood, haemolysis, and formation of histamine. If the patient should recover from the initial shock and collapse, of which histamine is believed to be an important cause, the perivascular haemorrhages resolve with the formation of much interstitial fibrosis. This fibrosis may affect all organs—liver, spleen, kidneys, heart—as well as the tissues in the immediate neighbourhood of the bite, and may result in chronic invalidism. Suppuration and gangrene, with repeated interruptions of healing, may occur at the actual site of injection. The prognosis depends on two factors: the amount and toxicity of the injected venom and the availability of specific antivenene.

The bite of the adder found in Britain is rarely fatal owing to the small dose and low toxicity of the venom injected. In the present case there were only local symptoms—toxic oedema and cellulitis, with haemorrhagic extravasations along the course of the lymphatics. The residual thickening of the muscles is presumably due to a slight degree of interstitial fibrosis.

Two Cases of Pontine Haemorrhage in Typhoid Fever

The complications of typhoid are so numerous that it has been truly said that the whole of medicine may be studied in one case. The following two cases reveal what appears to be a rare complication, as, apart from a brief note in Allbutt and Rolleston's *System of Medicine*, I have been unable to find any reference to it.

CASE REPORTS

Case 1.—A sergeant was admitted to a field ambulance on Sept. 30, 1941, and transferred to a general hospital on Oct. 3 with a history of continued pyrexia. On admission his temperature was 103° and his pulse 80; he was slightly delirious, so that his history of the onset could not be obtained. Blood culture gave a strong growth of *B. typhosus*. The disease, which was severe, ran a normal course till Oct. 6, when he had a profuse epistaxis accompanied by hiccup. When examined he was found to be semi-comatose, the pupils were pin-point, and all reflexes were absent. The temperature was 102.6°, and the pulse 84. The whole picture was that of a pontine haemorrhage, except that the temperature never rose above 103° and there was no glycosuria. His condition steadily deteriorated and he died 36 hours later. At necropsy the caecum showed gross typhoid ulceration almost amounting to gangrene, and there were numerous punctate haemorrhages scattered through the substance of the pons. There was, unfortunately, no record of when he had last been inoculated.

Case 2.—A dockyard worker was admitted to a general hospital on Oct. 30, 1941, and was diagnosed as suffering from enteric on the strength of continued pyrexia, papular rash, a rising titre to TO agglutinin, and the fact that he was one of a small group of eight, most of whom gave positive blood cultures to one of the enteric group. He had been inoculated with T.A.B. vaccine on July 15, 1941. Before admission he had suffered from severe headache, with slight neck rigidity, and on Nov. 1 it was noted that his pupils were pin-point and showed only slight reaction to light. He complained of diplopia at a certain angle, and there was a paresis of the left abducens nerve. Coarse tremor was present in the tongue and fingers, and the deep reflexes were brisk, including the jaw-jerk. The C.S.F. showed no pathological changes. On Nov. 11 he had a slight epistaxis. The disease ran a normal course, the temperature becoming normal about Dec. 15. However, on Dec. 29 he complained of a pain to the left of the sternum about the level of the fifth interspace. At operation a collar-stud abscess of the sixth costal cartilage was found, the pus from which gave a pure culture of *B. typhosus*. On Jan. 15, 1942, the pupils were pin-point, there was some weakness of the left lateral rectus muscle though diplopia was not complained of, all deep reflexes were brisk, jaw-jerk was still present, there was coarse tremor of fingers and slight tonic spasm in left arm and right leg but no mental changes. Unfortunately Service movements prevented a further follow-up.

COMMENTARY

By inference from Case 1 it is reasonable to conclude that Case 2 also had punctate pontine haemorrhages, but it is difficult to understand why this should have occurred. At the time of infection the two cases were separated by at least 100 miles; moreover, none of the others in Case 2's group showed any sign of cerebral haemorrhage, so that the action of a specially selective typhoid toxin does not appear to be feasible. Vitamin C deficiency is a possible explanation, though unlikely in Case 2 because the living conditions permitted of an ample supply of fruit and vegetables (an ascorbic acid estimation was not done). Failing these reasons, one is forced to conclude that there must have been some defect, histological or pathological, in the pontine capillaries and that the haemorrhages were analogous to the epistaxis which occurs in the early stages of some cases of typhoid fever—incidentally, in both the cases described.

D. C. WILSON, M.B., F.R.C.P.Ed.,
Surgeon Commander, R.N.V.R.

H.M. Stationery Office has published on behalf of the Department of Health for Scotland a 4d. pamphlet on the "Feeding of Infants and Pre-school Children" as a guide for use in wartime nurseries. It is commended in a foreword by Dr. Andrew Davidson, Chief Medical Officer of the Department of Health for Scotland.

Reviews

WAR SURGERY

Surgery of Modern Warfare. Edited by Hamilton Bailey, F R C.S Compiled by 72 contributors Volume II Second edition (Pp 517; illustrated. 40s., plus 9d. postage) Edinburgh. E and S. Livingstone. 1942

The first edition of this work appeared in parts which were completed in July 1941; the second consists of two volumes, the earlier of which appeared in May 1942 and was noticed in the *British Medical Journal* of June 27, 1942, p. 792. The second volume is now in our hands and comprises articles by thirty contributors, among whom it is pleasing to note that interspersed among the admirals and generals who have come down from the last war are quite a number of the younger officers of this. This work is a really fine effort on the part of its editor to keep those practising war surgery abreast of the most recent developments and provide them with an up-to-date reference book of a thoroughly practical character. So many books appeared early in this war which were largely reminiscences of the last, and were almost out of date as soon as they were published. An exception to such a criticism is this book of Mr. Hamilton Bailey's, produced with that high standard which we have come to associate with all the textbooks he edits, written by those with special experience of the various subjects which they consider, and brought up-to date by a critical editorial supervision. The second edition shows many improvements over the first.

Volume II of this second edition comprises sections ix to xx, and among the subjects dealt with are burns, wounds of bones and joints, wounds of the hand and foot, peripheral nerve injuries, and amputations. There are also articles on administration, on surgical diseases encountered in subtropical countries, on oto-rhino-laryngology in relation to war injuries, and on wounds of the eye and orbit. An appendix on very recent developments is particularly valuable: as an instance may be cited the article (p. 961) in which recent correspondence on the use of ligature and suture materials of cotton and thread is briefly but adequately discussed. This section, for which the editor himself is responsible, is full of useful information that brings the work right up to date. The production of the volume is excellent, the type clear, the references are full and easily found at the end of the chapters or as footnotes to the appendix, and the illustrations are many and well reproduced.

HANDLING OF CHROMOSOMES

The Handling of Chromosomes By C. D Darlington, F R S., and L F La Cour (Pp 165 8s 6d) London. George Allen & Unwin, Ltd. 1942

It is difficult to avoid the appearance of extravagance in praising this perfect specimen of what a laboratory manual can be at its best. Only masters of a subject could reduce to 165 small pages what others might well be unable to present in less than an indigestible encyclopaedia of four times the size. Only artists could achieve such elegance of presentation. Only publishers with a soul would in these difficult times do full justice to the book in the shape of good paper, clear-print, attractive arrangement, and superb plates; all, moreover, at such an astonishingly low price.

We are reminded that although the cell nucleus was discovered and named by Robert Brown in 1831, it was not till fifty years later that the chromosomes were seen. To-day it is known that they are the chemical organizers of life. It is in terms of their structure, behaviour, and functions that we must study reproduction, heredity, and development. The genes are among the largest molecules that the chemist has studied and at the same time they are the smallest living structures whose behaviour can be observed. In the teaching of biology, whether at school or university, there is nothing else which it is more important to demonstrate, or, what is far better, help the learner to study for himself. In this small volume every stage of treatment is dealt with from the collection of suitable plant and animal material to the drawing and photographing of the finished preparation. The authors have described relatively simple methods in careful detail, and nothing is omitted; to quote one example, there are tables showing the appropriate material for demonstrating the various structures and processes and showing also what is available month by month throughout the year. The apparatus described is as modest as is consistent with obtaining successful results.

It would be a dull student indeed who would not be impatient to start work as soon as the book was placed in his hands. But this is more than a manual for students. Research workers will find indications as to when and how more elaborate methods should be used. They will also find a most useful bibliography of recent reviews together with much information, some unpublished hitherto, which has never before been collected in a single volume.

ADVANCES IN PATHOLOGY

Recent Advances in Pathology. By Geoffrey Hadfield, M.D., F R.C.P., and Lawrence P Garrod, M D. F R C P Fourth edition. (Pp. 346, with 35 illustrations 18s.) London: J. and A. Churchill, Ltd.

"Garrod and Hadfield" is fast earning a place as the most important of the volumes in the "Recent Advances" series which began in 1924 with "Beaumont and Dodds." So much has happened in the four years that have passed since the publication of the third edition in 1938 that the authors have found it necessary to rewrite the greater part of this, the fourth edition. It is, indeed, becoming a commonplace for authors now revising books after an interval of four or five years to observe that the advances made in medicine through this period have been spread over such a wide field as to call for an almost complete revision of their work. We have clearly been through a period of almost unexampled activity, and can only hope that the war will at least provide a testing ground for much that is new, and not destroy the ferment that is at work in the mind of medicine.

The subject of inflammation is now dealt with in two chapters instead of one—welcome evidence that pathologists are looking afresh at fundamental problems which many people have looked upon as comfortably solved in standard textbooks. New chapters are given to vitamin deficiency diseases, to essential hypertension, to extrarenal azotaemia, and to crush syndrome. A new chapter on certain aspects of the pathology of the ductless glands has been contributed by Dr. E. F. Scowen, and there are new observations on such subjects as cancer, rheumatic fever. pneumonia, regional ileitis, and lipoid pneumonia. Messrs. Churchill are to be warmly commended for the admirable way in which they have produced this volume at a time when medical and scientific publishers do not receive the encouragement they should from the paper controller. We would draw special attention to the excellent half-tone reproductions. Anyone who wants to understand "the new pathology" cannot do without "Garrod and Hadfield."

Notes on Books

The publication of a fifth edition of Mr. A. P. BERTWISTLE'S *Descriptive Atlas of Radiographs: An Aid to Modern Clinical Methods* three years after the fourth indicates that there is a demand for this kind of atlas. It is a pity, therefore, that the opportunity was not taken to replace many of the older illustrations by ones of modern quality. This is the most important defect in the volume, that many of the illustrations are representations of the radiology of twenty years ago. There is a certain flamboyance in the preliminary matter in this book which the editor would be wise to curb in future editions. For instance, the remarks on the cancer campaign have little bearing on the main subject of the book, nor has the question "Is Abortion justified?" in the legend to the frontispiece. The section "Milestones in Radiology" will be of interest to those acquainted with the history of *x*-ray diagnosis. The publisher is Henry Kimpton and the price 42s.

A second edition has now appeared of Dr. R. D. LAWRENCE'S useful pamphlet *The Diabetic A B C Wartime Supplement*; it is published at 9d. by H. K. Lewis and Co.

Dr. MARGARET DOBSON'S *Binocular Imbalance* (H. K. Lewis and Co.; 10s. 6d.) is partly a restatement of elementary facts concerning binocular vision and partly an account of her personal practice in the diagnosis and correction of its disorders. It is of value in so far as it brings into a comprehensive scheme such new developments as dynamic retinoscopy, anaglyphs, and variable prism stereoscopes. There is much that is new in this monograph, but how much of this can be incorporated into actual practice is not at all clear.

SATURDAY OCTOBER 3 1942

INFLUENCE OF OCCUPATION AND ENVIRONMENT ON MORTALITY FROM PHTHISIS

The conditions under which the majority of the population live and work have been steadily, if slowly, improving during the present century, and during the past decade particular attention has been paid to social and environmental conditions. The reforms that have been introduced have been a large factor in bringing about the reduction in the rate of mortality that has been experienced during the past fifty years. Factors influencing health may be divided into two main headings—constitutional and environmental. The latter may be broadly subdivided into occupational and social risks. A distinct line between these two subdivisions cannot be drawn, because the social or economic environment is largely conditioned by the occupation followed. If the place of work or the rate of pay forces a worker to live in unhealthy conditions the extra risk involved must be attributed to occupation and may be regarded as an indirect occupational risk. In the past, crowding of the population in a small area around the works was common, and examples of this can be found in the coal, textile, and heavy industries. The occupational mortality section of the Registrar-General's decennial supplements have for years provided valuable information for comparative purposes. Although some diseases can be readily classified as specific risks inherent in the industry, such as chronic poisoning by lead and phosphorus, or due to the cumulative effects of long exposure leading to such morbid conditions as pneumoconiosis in anthracite miners and mule-spinner's cancer, our present knowledge of the occupational risk is imperfect. The method of selecting recruits varies from industry to industry; some occupations demand a high standard of physique and some impose no standard. The importance of selection must be stressed, and because the death rate of a particular occupation is high it cannot be inferred that the trade is inimical to health, because the excessive mortality may be due to indifferent physique allied with a low economic standard and poor domestic conditions.

Hay was the first to attempt to differentiate between the occupational and the environmental risk. He used the experience of the city of Aberdeen during the ten years 1900-9, and compared the phthisis death rate among males in twelve occupations with that of wives and widows and the unmarried children of men who followed these occupations; they were exposed to the environmental but not to the occupational risk. His data showed that the phthisis rate was much greater among males than among the wives and widows; the range was 1.1 to 5.7 for males and 1.1 to 2.1 for wives. Within the limits of his data, which Hay recognized, it would appear that the risk of phthisis in the occupations with a high mortality was of a direct occupational nature, as the married women showed no corresponding excess. Cheeseman,[1] in an interesting paper, has pursued this line of investigation over a wider range of occupations. His observations are based on the data published in the Occupational Supplement of the Registrar-General for 1930-2, and, as for Hay's data, the male mortality was based on the experience of all males, married and single. The occupations of the males were divided into five groups according to whether their standardized mortality ratios from pulmonary tuberculosis were (1) significantly greater, (2) probably significantly greater, (3) not significantly different, (4) probably significantly less, (5) significantly less than the ratio for all males. The standardized mortality rates for wives were similarly subdivided. A combination in any occupation of a significantly greater mortality for males with a mortality for the wives significantly less could be taken as evidence that the direct occupational was more important than the environmental risk. No such occupation was found. Hairdressing was the only occupation with a significantly excessive male ratio associated with a ratio for wives that was probably significantly smaller than that for all married women. Altogether 43 occupations were studied, and of the 19 occupations in which the male phthisis was in excess there were 10 in which the wives had a similar experience and 2 in which the values for the wives were subnormal. In 17 occupations the male experience was below normal, and for 15 of these the ratio for wives was either equal to or in defect of the average for all wives. From the data examined it was concluded that the direct occupational risk could not be differentiated from the environmental, possibly because of imperfections in the statistics.

The failure to distinguish easily between the occupational and the environmental risk emphasizes the importance of the social and economic aspect. A great rebuilding programme will have to be faced after the war, when the housing problem will be acute; it is essential that the relation which exists between the home environment of the workers and mortality should be given full consideration. And however "ideal" the home may be it must be remembered that the size of the rent must not be such as to leave insufficient money for the purchase of proper food and clothing. The relation between social and economic environment and respiratory tuberculosis can be shown by considering the five social classes of the Registrar-General. Mortality increases progressively as the social class decreases. Taking the standardized mortality ratio of all males aged 20-65 as 100, the standardized mortality ratio of social class I is 61, and for social class V 125. The corresponding figures for married women are 52 for social class I and 132 for social class V.

SHOCK TREATMENT IN PSYCHIATRY

The last decade has seen remarkable progress in the physical treatment of the psychoses. A short time ago it was only the increasingly rare cases of general paralysis that offered us the opportunity of effective intervention and cure. Out-patient departments were combed for hopeful cases of neurosis, where the healing art in the form of psychotherapy might be brought to bear with some prospect of success. Even the most recent case of schizophrenia or affective psychosis received only a symptomatic and expectant form of treatment, relying exclusively on the vis medicatrix naturae. The situation is very different to-day. Acute psychoses of recent onset now present the most favourable clinical material we have; and the much wider experience of neurosis in all its forms which has been forced on us by the war has convinced many previous enthusiasts that neurosis, whether inborn disposition or environmentally determined habit, is more often than not an extremely refractory therapeutic problem.

---

[1] *J. Hyg.*, Camb., 1942, 41, 463.

A recent manual by Drs. Jessner and Ryan[1] marks this change of attitude, and describes the therapeutic techniques by which it has been brought about. Insulin treatment of schizophrenia and convulsive treatment of depression have obviously come to stay, at least until still more effective measures have been devised. Their efficacy has been and continues to be energetically debated; but the statistical evidence which has been accumulating now for more than seven years approaches more and more nearly to unanimity in their favour. It is now time that every physician concerned with the treatment of psychotic patients should be familiar with their indications, technique, and complications; and this book provides a valuable step towards a more general education in this direction. Treatment is worth while, and it is essential that it should be properly planned. The expectation of life for a schizophrenic of twenty-five years is about thirty years, which if spent in hospital will cost the community about £1,700. The annual incidence of schizophrenia is large enough (over 2,000 in 1932 in England and Wales), and the prospects offered by treatment are favourable enough, to make any adequate acute treatment centre a communally profitable enterprise. On the other hand, the results obtained by haphazard playing around with insulin and convulsion cannot be compared with those obtained by system and planning.

The usefulness of these physical methods of treatment emphasizes the kinship of psychotic with general medical illness. We are not deterred by fear of relapses from treating tuberculosis, diabetes, and cardiac disorder by the best methods we know, and the same attitude should be more general in psychiatry. There should be the same degree of discrimination and clinical judgment in the prescription of treatment in psychiatry as in general medicine. As it is there is a tendency to regard convulsive therapy as a cure-all, or something that must be tried in every case. The wide introduction of the simple, foolproof, and inexpensive electrical apparatus into psychiatric hospitals and out-patient departments all over the country is both the welcome sign and the cause of increased therapeutic interest; it is likely that as a result many patients will be spared months and even years of misery and illness. But therapeutic enthusiasm can be uncritical. Not so long ago[2] we stressed the need for agreement upon both diagnostic and prognostic standards, and for statistical analysis. Until this agreement has been secured we must beware against being misled by "clinical impressions." The method is being employed for the treatment of such refractory material as the chronic obsessional, and, because the proper facilities are lacking, for the early schizophrenic. This latter use instead of insulin is, except in the rarest cases, really disastrous; for it induces a fallacious feeling of well-directed effort, when, at best it secures only some symptomatic improvement, more usually wastes valuable time, and not infrequently does actual harm. The administration of convulsion therapy often clears up depressive symptoms in a variety of syndromes—organic, schizophrenic, and reactive—as well as in the typical endogenous and involutional melancholias. On the other hand, it is rather ineffective in the treatment of thought disorder, paranoid symptoms, and depersonalization. In so far as these symptoms depend on a fundamental depression, they may clear up too; but if separately determined they are likely to be but little affected. Nevertheless, while convulsive treatment is being more and more actively employed, insulin treatment is being relatively neglected. The reason for this is probably nothing more than the great difference in administrative and technical difficulty of the two methods. But the tendency is to be regretted. For the depressive, for whom convulsive treatment can do so much, is likely to recover eventually, treatment or no treatment; while the schizophrenic, if he is deprived of insulin treatment in the earliest months of the illness, faces a high probability of progressive deterioration and life-long asylum care. It is to be hoped that the very practical manual of treatment by Jessner and Ryan will do something to remedy this undesirable state of affairs.

PROGNOSIS IN REGIONAL ENTERITIS

Diseases of the small intestine present problems not easy to unravel. In an article in this *Journal* in 1913 T. K. Dalziel,[1] describing nine cases of "chronic interstitial enteritis," ended with the words: "I can only regret that the aetiology of the condition remains in obscurity, but I trust that ere long further consideration will clear up the difficulty." In 1933—twenty years later—P. W. Brown in America suggested the title "regional enteritis" for this same condition, which a year before Crohn had described and to which his name has since been widely given. Now, almost thirty years later, Brown, summarizing with C. J. Donald[2] a total of 178 cases already seen at the Mayo Clinic, is still forced to write: "We deplore the fact that we have no knowledge of the aetiology of the disease." But we at least now have many accurate and detailed reports of its symptomatology and pathology. Briefly stated, the condition is characterized by abdominal pain, diarrhoea, fever, anaemia, development of fistula, loss of weight, nausea, and vomiting. Many cases resemble, and are operated upon for, acute intestinal obstruction, which may often in fact occur. Other cases are mistaken for acute or chronic appendicitis, ulcerative colitis, ileo-caecal tuberculosis, actinomycosis, or nervous diarrhoea. In some patients a mass develops in the right iliac fossa, though this is in fact a late occurrence. Earlier, the intestine is thickened and oedematous, with rigidity, adhesions, abscess formation, or fistula. The mesentery is thickened and shows hyperplastic glands; N. C. Tanner,[3] writing recently in this *Journal*, emphasizes these changes as of particular importance in both treatment and perhaps causation.

From Brown's series of cases a number of interesting conclusions can be drawn, though he is unable to throw much fresh light upon the condition. In prognosis, with which he is specially concerned, he stresses once more the seriousness of the condition, which tends to progress by remissions and exacerbations, and to spread both up and down the intestine from its point of origin. In 92% of Brown's cases this was in the terminal ileum (ileitis), but it may be at any point in the small intestine. As the disease progresses, increasing nutritional defect may arise and in advanced cases gross failure of absorption occur. At present we do not know how to prevent the condition, and the only effective treatment is surgical. No medical treatment is more than palliative, though the value of a high protein diet with additional vitamins is undoubted both before and especially after operation. Brown stresses the need for adequate supplementary supplies of the vitamin B complex.

The results of treatment depend upon several factors—one of which at least would appear to be the thoroughness of the operation. The more radical the excision of the inflamed intestine and the diseased mesentery, the more hopeful appears to be the prospect. When further resections are necessary after the first attempt the mortality is high, and Brown records only 14 of 23 patients so treated as surviving. Short-circuiting alone may dramatically relieve—and even appear to cure—the condition for a time, and in an acute phase this is often all that can be done. In the more chronic stage, however, immediate resection may be possible or a deliberate two-stage operation be performed. Brown's figures suggest that a two-stage is better than a one-stage operation. Colp, Garlock, and Ginzburg,[4] however, reporting 40 cases treated by ileocolostomy with exclusion, record no operative mortality and recession of the disease in the excluded loop in a high percentage; at the same time they emphasize the importance of dividing or excluding the ileum well above the apparently diseased area, because the proximal few feet of gut above the lesion may be involved even though appearing to be normal. In Brown's opinion short-circuiting alone offers success in less than 50% of cases, and he notes that the necropsy records at the Mayo Clinic reveal no instance of healed chronic regional enteritis. At the time of his report, only 14 out of 45 short-circuited patients were well, and half of these had in fact been in bad health within a few years of the operation. In his opinion such patients should be kept under observation, and even when the patient is in apparent good health it is wiser to resect the gut rather than wait until an exacerbation of the disease makes this both more dangerous and more imperative.

The continuance of anaemia, failure to gain weight, and diarrhoea are ominous signs, especially after operation, though persistent diarrhoea is a frequent sequel of ileocolostomy and not alone of serious significance. The importance of careful and, if necessary, repeated radiological examination in obscure cases presenting symptoms such as these needs little emphasis, and has been recently mentioned in an account of two cases by Pratt and Simpson,[5] who also recommend the adoption of a two-stage operation in treatment. In over 70% of Brown's series positive evidence of disease was given by *x*-ray examination—the great majority by means of the barium enema. If the condition begins, however, above the ileum, even a careful barium meal examination is likely to miss it at first, but fortunately less than 10% of cases arise at any site other than the lower ileum.

Bearing, therefore, the possibility of the disease in mind, and with the aid of skilled radiography, early diagnosis should be more common; combined with this, radical and determined surgery may legitimately be expected to improve the prognosis and the, at present, high mortality, which was approximately 10% in Brown's 178 cases.

A GREAT EPIDEMIOLOGIST

Those who had the privilege of Dr. Wade Hampton Frost's friendship will need no reminder of the pain his premature death caused. A still wider circle who have read a most judicious and well-edited selection of his papers[6] will realize that the world has lost a great investigator and teacher. These papers mirror the evolution of epidemiological science in a sagacious, critical mind; the image is sharp because Frost had command of an admirably clear and scholarly prose style.

The earlier papers are models of descriptive epidemiology; sound and accurate official reports. Few become first-rate epidemiologists who have not had the discipline of reporting to superiors apt to prefer literal accuracy to scientific imagination; Frost had had the additional advantage of experience in country practice. Epidemiology is indeed the study of groups, not individuals, but it is well to know something of the characteristics of the individuals merged into groups. The papers on typhoid fever in Williamson and septic sore throat in Baltimore belong to this period, which ends with the elaborate report on poliomyelitis in Iowa. Frost was conscious of the difficulty of a complete enumeration of group characters, because of the protean clinical manifestations of the disease, and soon to face the difficulties in an even worse form. The next group of papers had their origin in the apocalyptic events of 1918-19, the great influenzas. He was faced by problems which could not be solved by analysis of official and ostensibly exhaustive data. One may register deaths on a nation-wide scale, but hardly illnesses, at least with enough particularity to satisfy a critical mind. So one has recourse to sampling, to the intensive study of selected groups. This involved a more elaborate statistical technique than exhaustive enumeration, and Frost steadily widened his biometric knowledge. He had the good fortune to be associated at Johns Hopkins (from 1919 to his death) with such biometricians as Lowell J. Reed and the late Raymond Pearl and, without ceasing to be primarily an epidemiologist, gave proper weight to statistical considerations. It is not that his papers became more statistical in the sense of including more tables of figures—actually the later papers have fewer tables—but they become more quantitative in the best sense of the word; the numerical analyses *tell* more. This increased power of handling data quantitatively is seen when he returns to the relatively simple problem of diphtheria in Baltimore—absolutely complex but without the horrifying complexity of influenza. The deduction of a *measure* of decreasing incidence in a partly immunized population is skilful and yet simple. Similarly, the paper on familial aggregation of infectious diseases is an excellent appraisement of a method suggested by Chapin.

In his last years Frost turned to the epidemiology of long-term infections, particularly of pulmonary tuberculosis, having perceived the importance of an actuarial method of analysis. A comparison of these papers with those of very good writers a generation earlier will enable the reader to appreciate the immense improvement of technique which the method of sampling, properly controlled, has made possible. It may be said—undoubtedly Frost himself would have said—that none of these papers chronicles a dramatic revelation like that of Frost's great hero, Dr. John Snow. The problem of poliomyelitis is still not completely solved; that of influenza still challenges us. Yet the oft-misused adjective "great" is fairly applicable to Frost's achievements. By precept and example he raised the level of epidemiology as a branch of medical science, bringing it into a position to command the respect of contemporaries. His loss must be felt for years, but he built so well that the school he founded at Baltimore will surely continue to be one of the focal points of epidemiological education.

LOW PHOSPHORUS DIET AND EXPERIMENTAL RICKETS

Rickets may be the bane of the paediatrician and social welfare worker, but by the interest which it has aroused among biochemists it has added considerably to our knowledge of biological processes and not least of the part played by phosphorus, an element which makes its presence felt in many biochemical dramas. In order to describe the physiological significance of an indispensable nutrient, observations must be made on suitable animals restricted to diets extremely deficient in the element to be studied but adequate in other respects. While this method has been often employed with lime and other minerals it has not hitherto been effectively used for phosphorus. It is true that the cereal rachitogenic diets introduced by Sherman, McCollum, and others produce a phosphorus deficiency in the growing animal owing to the fact that much of this element is present as phytin, which varies greatly in its digestibility. This, however, introduces a factor of uncertainty, and in a recent series of papers[1, 2, 3, 4, 5] from different laboratories in the U.S.A. some attention has been paid to the preparation of diets containing a very small amount of total phosphorus, approximating to an absolute deficiency. These diets with and without an associated vitamin D deficiency have been used in experimental work on rats and puppies and have yielded conflicting but interesting results.

[6] *Papers of Wade Hampton Frost, M.D.: A Contribution to Epidemiological Method.* Edited by Kenneth F. Maxcy, M.D. New York: The Commonwealth Fund; London: Oxford University Press (\$3.00 or 16s. 6d.)

Within a few weeks progressive deterioration in the general health of the animals (rats) was apparent. The coats became rough and greasy, muscular activity was diminished, and ultimately walking, standing, and even breathing became more difficult and painful; examination of the skeleton revealed extreme rarefaction. In the earlier phases the metabolic and clinical manifestations of rickets were produced when vitamin D was absent from the diet. The results of adding this vitamin to the food varied with different workers. Schneider and Steenbock[1] found that rickets was prevented in rats, but Zucker and his colleagues,[4] while agreeing that there was no naked-eye evidence of rickets, observed that a supplement of vitamin D was incapable of maintaining the normal mineral composition of the bone. In puppies, on the other hand, Freeman and McLean[5] found that on a low-phosphorus diet florid rickets was produced whether or not the vitamin was given. It is obvious that there is a species difference. Zucker, however, stresses the fact that the absence of anatomical signs of rickets does not necessarily indicate normal ossification. This, of course, is of great interest in the ever-recurring discussion on the criteria of rickets in the infant. It is generally agreed that the *x* ray is more effective than clinical examination in detecting mild degrees of the disorder. The question arises as to the desirability of using biochemical tests such as an increase in plasma phosphatase as a diagnostic indication even when there is neither clinical nor radiographic evidence. Freeman and McLean[5] studied the distribution of phosphatase by histological methods. From their sections there appears little doubt that osteoid tissue is devoid of phosphatase, which is found in abundance wherever osteoblasts are abundant. There is clearly room for further work on these lines, especially to determine whether there is any relation between the bone phosphatase and the concentration of this ferment in the plasma.

Some interesting facts are available with reference to the interchange of phosphorus between bone and soft tissues. According to Schneider and Steenbock,[1] the addition of vitamin D to a low-phosphorus diet, while preventing rickets and causing an increase in serum phosphorus, led to a complete inhibition of growth. They suggest that the anti-rachitogenic effect is due to the stimulating effect of vitamin D on phosphorus utilization in the skeleton, thereby depriving the soft tissues of their quota of this element. Day and McCollum,[3] on the other hand, found that, despite an actual loss of phosphorus from the body, growth continued for some weeks. As the percentage content of phosphorus in the non-osseous tissues remains constant, it would appear that, contrary to the conclusion of the other workers, phosphorus is diverted from the bone to the soft tissues even when there is an absolute deficiency. This utilization of bone phosphorus is, however, very inefficient, as a great loss of body phosphorus occurs. Curiously, the faeces accounted for practically all the phosphorus loss, whereas three-quarters of the ingested calcium was voided in the urine. These results may be considered with the finding that in puppies with low-phosphorus rickets there was actually a hypercalcaemia. In spite of the increase in serum calcium the calcium–phosphorus product was reduced, indicating a slight undersaturation of the serum with calcium phosphate. It is easy, therefore, to understand why there is little calcification and why, with adequate absorption of lime, there is excessive urinary output.

So far, low-phosphorus diets have been exploited only for the study of mineral deficiencies allied to rickets. There still remains the exploration of such fields as parathyroid activity, the problem of phosphorylation in connexion with carbohydrate metabolism, and the absorption and excretion of lead and other substances.

A WORD TO CORRESPONDENTS

Once again readers are urged to keep check on their pens. The paper situation is very difficult, and we see no prospect of an adequate supply. In March last our meagre ration suffered a drastic cut, which leaves the *Journal* with little more than 50 pages a week for all the purposes of a professional organ of information and opinion serving 41,000 members at home and abroad. Advertisements are cut down to a bare minimum; the size of type has been reduced to the limit of comfort if not of legibility; and rigorous economy of space is exercised in every direction. Meanwhile, the inflow of articles and letters has grown apace. It is natural that members should want to express themselves on urgent questions of the day, and one of the *Journal*'s functions is to give them the means for doing so. But the growing restriction on paper supplies makes it impossible to print more than a small proportion of the many letters received or to acknowledge and return those that cannot appear. Correspondence on medical planning, on a State Medical Service, and on certification has far exceeded the space available, and still the letters come by every post. We do not like to disappoint those who commit their thoughts to writing in the rare leisure of a busy life, and we ask them to accept this collective apology. So long as there is not nearly enough paper to go round, letters (and articles, too) must be fewer and briefer.

Prof. D. Keilin, F.R.S. (Quick Professor of Biology in the University of Cambridge), and Sir Henry H. Dale, P.R.S. (retiring Director of the National Institute for Medical Research) have been appointed members of the Medical Research Council in succession to Prof. L. J. Witts, F.R.C.P., and Prof. C. R. Harington, F.R.S., who retired in rotation on Sept. 30. Sir Charles Glen MacAndrew, M.P., has been appointed a member of the Council in succession to the Rt. Hon. James Gray Stuart, M.P.

War Medicine Series

The paper printed below is based on a lecture which was one of a series recently given at the British Postgraduate Medical School, Hammersmith

LOUSE-BORNE TYPHUS FEVER

BY

Sir J. W. D. MEGAW, M.B., D.Sc., I.M.S.(ret.)

When the names "typhus" and "typhus fever" are used without qualification in this article they refer to louse-borne typhus, which is the chief member of a family called "the typhus group of fevers." The other typhus fevers are closely related to the louse-borne disease in being caused by rickettsial bodies, in having the same type of clinical features, and in producing similar pathological changes in the body. They differ sharply in being primarily diseases of lower animals; their viruses are transmitted to man as a secondary incident through fleas, ticks, or mites which are parasites of the infected animals. Because of this essential difference these fevers cannot give rise to epidemics such as readily occur in louse-borne typhus, which is directly transmitted from man to man by a human parasite, the louse. The non-epidemic, or "zootic," typhus fevers are of minor importance as war diseases, but they sometimes cause trouble by being mistaken for the human louse-borne disease, from which they may be indistinguishable by the methods of diagnosis available to isolated medical men.

Louse-borne typhus has a number of synonyms, including typhus fever, epidemic typhus, exanthematic typhus, louse typhus, historic typhus, and classical typhus. It should be noted that when German writers use the name "typhus" without special qualification they refer to typhus abdominalis, or typhoid fever; so also they use the names "pseudo-typhus" and "paratyphus" with reference to typhoid.

Definition.—Louse-borne typhus is a disease caused by *Rickettsia prowazeki*, which is conveyed from man to man by human lice. In most of the cases there is high fever lasting from 10 to 16 days, with early and pronounced nervous symptoms and a characteristic rash. The disease often occurs in epidemics, but it may be endemic or sporadic. Mild attacks which do not conform to the classical type are so frequent and also so important that a detailed definition based on the "typical" form of the disease would be misleading rather than helpful.

History and Distribution

History.—About a hundred years ago typhoid fever and relapsing fever were first recognized as distinct diseases; previously, "typhus fever" or one of the scores of synonymous names served as a designation for any severe epidemic fever other than those that could be recognized by their special characteristics. Since the middle of the fourteenth century there have been many accounts of epidemics of fevers of these kinds in Europe, occurring chiefly in times of war or famine. In some of these accounts typhus can be recognized; others paint a confused picture made up of a mixture of typhus and relapsing fever or of typhus and typhoid. Since 1844 typhus has been recognized as a clear-cut entity, so that Murchison's description in 1862 of epidemics of the disease can hardly be improved on at the present time. The contagious nature of typhus was widely accepted, but vague ideas prevailed about the cause of the disease: for example, Murchison held that a poison was generated spontaneously in the body as a result of overcrowding and bad ventilation. In 1909 C. Nicolle produced the disease in a chimpanzee by inoculating the blood of an infected person; he also transmitted the infection from this animal to other monkeys by lice. The causal organisms were rather vaguely described by Ricketts and Wilder in 1910; Prowazek studied them closely; and in 1916 Da Rocha Lima described them accurately and called them *Rickettsia prowazeki*. The first agglutination test was carried out by Wilson in 1910: he found that the serum of infected persons agglutinated certain bacteria of the coli group which he had isolated from typhus patients, but he pointed out that the serum response did not prove that the organisms were the cause of the disease. In 1916 Weil and Felix, using a different bacillus, *Proteus* X 19, described the reaction which goes by their names. Recent work has been concerned chiefly with the prevention of the disease, especially by protective inoculation.

Distribution.—The disease is cosmopolitan; it is apt to break out in louse-infested communities in many parts of the world in which cool weather conditions prevail at some season of the year. In tropical countries, for some unexplained reason, typhus is decidedly uncommon except at high altitudes. On the whole it is a cold-weather disease, and although epidemics may occur in hot weather it would appear that cold or cool weather is a necessary preliminary to the widespread transmission of infection. More cases occur in the later part of the cold season and the early hot season than at other times, but there have been many exceptions to this rule. Some countries have remained remarkably free from the disease in spite of the conditions being apparently suitable for the spread of infection; for example, no great epidemics have been reported from India, even from crowded louse-infested communities in which great epidemics of relapsing fever occur at intervals. In the countries of Western Europe, in Canada, and in the United States of America the disease is now rare in times of peace; evidently the reduction in the degree of louse infestation of these countries has brought about conditions in which transmission does not readily occur. Epidemics have been reported in recent years from Poland, Russia, Ukraine, Rumania, French North Africa, South Africa, Korea, Manchuria, North China, and Asia Minor. Cases have also occurred in Mexico, Bolivia, Peru, and the high altitudes of Colombia. Official reports for May and June, 1942, show that severe and widespread epidemics were then raging in Algeria, Tunisia, and French Morocco, and that outbreaks were occurring in many localities in Spain, Hungary, Rumania, and Bulgaria; cases were also reported from Shanghai, Iraq, Iran, Turkey, and Lyons in France. No official reports are now available from Russia or countries in German occupation, but there is plenty of evidence that the disease is causing great anxiety even in Germany itself, where, in spite of elaborate precautions, many groups of cases have occurred among the soldiers engaged in guarding prisoners of war. In one instance 23 of 25 persons employed at a camp near Berlin were attacked.

In the eastern countries of Europe there is a return to the conditions which caused devastating epidemics during and after the war of 1914-18. These conditions were the existence of infection, great movements of population, malnutrition, overcrowding, lack of facilities for personal cleanliness, and louse infestation. In these circumstances typhus fever must be imposing a severe strain on the German and Russian efforts to keep it under control.

In this country the disease still smoulders in some places, and so long as louse infestation is allowed to persist there is need for constant vigilance by the medical profession and the public health services. Persons of all ages and of both sexes are equally susceptible, but attacks in young children are usually mild and so are often missed. So also in endemic areas, adults who have had previous attacks are likely to get the disease in a mild form, and thus infection may persist without being detected.

The Virus

The rickettsiae of the disease have been isolated from the blood of patients during the febrile stage, also in some cases during the last two or three days of the incubation period; the virus usually disappears with or just before the fall in the temperature, but occasionally persists for a day or two in early convalescence. Infection is conveyed from man to man by human lice, chiefly, if not entirely, by the body louse. The louse cannot transmit infection till 5 to 10 days after biting an infected person; it then remains infective for the rest of its life. The rickettsiae are scanty in the human body, but multiply exceedingly in infected lice, chiefly in the cells of the gut. They are small organisms resembling bacilli or cocci:

they stain well with Giemsa's reagent and are Gram-negative. They do not grow in ordinary culture media, but only in the presence of living cells: for example, in tissue cultures or in the yolk sacs of developing chick embryos. In the latter they multiply rapidly, so that suspensions of the yolk sacs may be heavily loaded with rickettsiae a few days after inoculation. Monkeys are susceptible to infection: the virus can be maintained in guinea-pigs for an indefinite number of transfers by intraperitoneal inoculation, but the disease is seldom fatal to the animals and seldom causes scrotal swelling such as results from inoculation with the rickettsiae of flea-borne typhus. White mice are susceptible to inoculation by the tracheal route; the animals get severe pneumonia, and enormous numbers of rickettsiae are found in the consolidated lungs.

The virus is normally transmitted through the skin from infected lice. The exact mechanism of transmission is doubtful; some workers believe that the organisms are not introduced into the body in the act of biting, but rather by the entry of infected faeces or of fluids from the crushed bodies of the insects through the site of the puncture or through scratches. The faeces of infected lice contain enormous numbers of rickettsiae, which can survive for a long time in the dried faeces. It is therefore possible that infection may occasionally be conveyed through contact with the faeces or through the inhalation of dust particles resulting from the drying of the faeces. Some German workers have recently recorded cases in which they held that transmission by the lice themselves could be excluded. These observers emphasize the need for disinfection of the skin and clothing of the patients rather than mere disinfestation by methods which fail to kill the rickettsiae. Another matter of importance to medical attendants is that the blood of the patient is infective, so that if accidentally smeared on the fingers when making blood films it may cause infection. A case has recently been recorded in which the disease was caused by the transfusion of blood from a donor who happened to be in the incubation period of the disease three days before the onset of his attack.

Immunity.—An attack confers immunity, which is complete for a considerable time but gradually wears off, so that a second attack may occur; this is usually much milder than the original illness. Mild or unapparent attacks in persons with partial immunity are believed to be important sources of infection in endemic areas.

Pathology.—The characteristic lesions are tiny nodules in the walls of small blood vessels, especially of the brain, skin, and kidneys: the nodules are made up chiefly of large and small mononuclear leucocytes and of partly necrosed endothelial cells of the blood vessels. Necrosis of the vessel walls at the sites of the nodules is the chief cause of haemorrhages and petechial eruptions. The nodules also cause interference with the blood supply of the brain, heart, and other organs, and so are probably responsible for many of the chief features of the disease.

Clinical Features

Most of the cases seen in severe epidemics conform to a fairly uniform type, though there are wide variations in severity. Sporadic attacks and cases in endemic areas, especially when they occur in children, are often so mild that they are very likely to be missed by medical men whose mental picture of typhus is based on descriptions of "typical" cases. The figures given in parentheses in the following account are based on reports of epidemics; they are not applicable to mild outbreaks. For a detailed account of the symptomatology the textbooks must be consulted.

Incubation Period.—This is usually 8 to 12 days; the extreme ranges are 5 to 23 days. As a rule the longer the incubation period the milder is the attack.

Signs and Symptoms

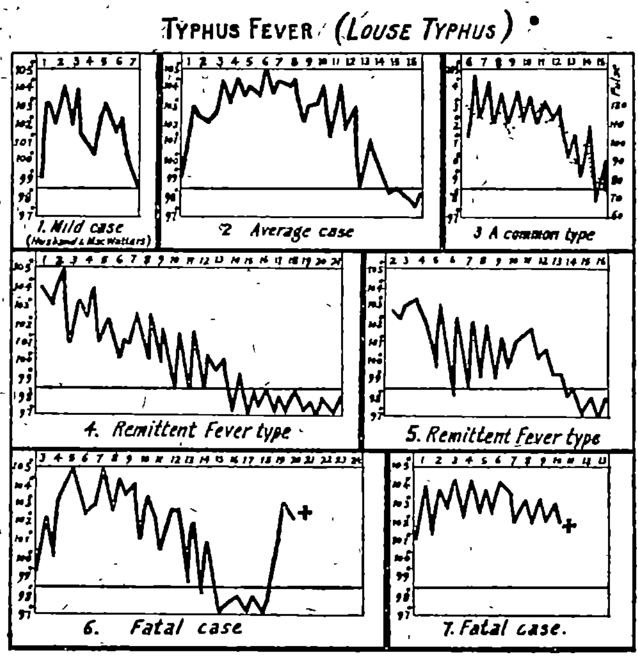
The chief features of cases seen in adults during severe epidemics are: The onset is usually sudden or rapid, with chill, shivering, or rigor (60 to 80%), severe frontal headache (90%), and pains in the back and limbs. Vomiting frequently occurs (25 to 50%). There is often suffusion of the face with swelling of the eyelids and injection of the conjunctivae. At first drowsiness or mental confusion is present, succeeded by stupor or delirium in many of the severe cases. Insomnia is frequent (50%). The temperature rises rapidly, reaching its maximum of 103° to 105° F. within two or three days and then remaining high, with daily remissions of 1 to 3 degrees for 8 to 12 days. Occasionally the temperature falls to normal for a few hours before the end of the first week; but, apart from this pseudo-crisis, the fever runs an uninterrupted course in most cases. The throat is often red (30 to 75%), the tongue and mucous membranes of the upper air passages are usually dry, and the latter may be distressingly irritated. Bronchitis is frequent (80 to 90%). Meningism is not uncommon. The spleen is sometimes palpable.

The rash is often the first diagnostic feature; in some outbreaks it has been reported as being absent in about 10% of the cases. In pigmented skins it can only be detected when it is pronounced. It appears suddenly, as a rule between the third and fifth days; in rare cases it is seen on the second day, and it may be delayed till the eighth or ninth day. Often it is preceded by a faint mottling of the skin, then pink or bluish-red macules appear on the sides of the chest, back, and shoulders, rapidly extending to the rest of the trunk and often to the arms and legs. The spots are seldom raised; at first they disappear on pressure, but soon cease to do so; at the same time their colour changes to deep red and then to brown. In severe cases there is often a petechial haemorrhagic point at the centre of each spot; this is surrounded by a brownish mottling. After a few days the spots begin to fade, but brown staining may persist for some days or even weeks. The spots may be few and difficult to detect; usually they are numerous, and in severe cases they may be very profuse. Exceptionally, the eruption is maculo-papular or papular; in severe cases it may consist of purpuric patches of varying size. The distribution of the rash is important in diagnosis. The trunk, especially the sides of the chest or back, is the favourite site; there is extension to the arms and legs in about three-fourths of the cases, but the face is affected in only a few patients (about 4%). The palms and soles are very rarely involved (about 2%). In some recent outbreaks extension to the face, palms, and soles has been relatively frequent.

The pulse soon becomes feeble, it may be slow in proportion to the temperature; the blood pressure falls, so that systolic readings of 80 to 100 are usual. Occasionally there is leucopenia, but a moderate degree of leucocytosis is usual; very high counts of 20,000 or more occur only in very severe cases. The blood tends to become concentrated; the haemoglobin readings and red blood cell counts may be abnormally high even when blood destruction is progressing. Febrile albuminuria is usual; true nephritis is infrequent, but has been reported as fairly common in some epidemics. Red blood cells in varying numbers are found in the centrifugalized urine; in severe cases there may be obvious haematuria. The leucocytes of the cerebrospinal fluid are slightly increased in mild cases—considerably so in severe attacks, in which a good deal of albumin may also be present.

The most striking feature of the disease is the rapidly progressing deterioration in the mental and physical condition; before the end of the first week the patient is often in the "typhoid state," with great prostration, low muttering delirium or coma, tremor of the tongue and tendons, and absence of response to external stimuli. Active noisy delirium and great restlessness may occur: in this condition there is an added strain to the already enfeebled heart. The breathing is usually hurried even when pneumonia does not occur; the heart sounds are feeble, especially the first sound, which may be inaudible. Even in relatively mild attacks mental disturbance and physical weakness are conspicuous features; their early onset and rapid progress are in contrast to what happens in typhoid fever. Meteorism is unusual in typhus patients. In recovering patients improvement usually sets in rapidly or suddenly; the temperature falls by rapid lysis or by crisis about the twelfth to the sixteenth day and at the same time the mental condition improves and the appetite returns. At this stage special care is needed because the patient feels so much better that he is tempted to take liberties while his heart is still very feeble. In some cases the mental condition does not clear up till some days or even weeks after the fall of the temperature: slow cerebration, deafness, and tremors of the muscles are the chief symptoms in such cases.

Most of the deaths occur between the tenth and the seventeenth day; it has been stated that the eleventh day is especially critical, but in some epidemics more patients have died after than before the fall in the temperature. A few of the types of temperature curve that may occur are shown in the accompanying chart.



Mild Attacks.—These are far more common than would be gathered from descriptions of the disease that are based on experience of severe epidemics: in many outbreaks severe attacks are quite exceptional. Cases in children and sporadic attacks are often so mild that they are not recognized. In surveys of suspected areas ambulatory cases or even unapparent attacks are sometimes discovered by the Weil-Felix test. The mildest cases that are likely to be recognized in ordinary conditions are those resembling an attack of influenza: the patient has fever, with pains in the back and joints, redness of the throat, headache, and lassitude. There may or may not be a rash. The fever lasts a week to 10 days, the rise and fall in the temperature are often gradual, and apart from a positive Weil-Felix reaction no reliable diagnostic indication may be present. In some outbreaks the cases are more characteristic; they have a general resemblance to the severe attacks seen in epidemics, but the signs and symptoms are all of a milder type, the temperature does not rise so high, and the fever lasts from 10 to 13 days. Complications are rare and convalescence is rapid. Even in groups of cases in which moderately severe attacks occur, the case-fatality rate may be negligible except in elderly patients. In the absence of overcrowding, malnutrition, and very heavy louse infestation the average severity of the disease is by no means great. Brill's disease appears to be a mild form of louse-borne typhus. Although this disease was first described by Brill of New York as long ago as 1897 its true nature has only recently been discovered. Zinsser has shown that the virus is of the same type as that of louse-borne typhus and that more than 95% of the patients had originally come from places in Europe in which typhus fever was endemic. This suggests that the disease may be a late recrudescence of infection which has lain dormant for years in the patients. Although 500 cases have been reported from New York since 1910 there is no record of infection having been transmitted to contacts. Cases of the same kind must occur in other countries, including, in all probability, the United Kingdom. Clinically the disease is mild typhus fever, but it can occur in the absence of louse infestation.

Fulminating Attacks.—At the other end of the scale are the virulent and rapidly fatal attacks. These occur in severe epidemics and usually in elderly persons debilitated by malnutrition. The patient may die within 3 or 4 days of the onset—sometimes before the rash has time to appear, but more often after the precocious appearance of a haemorrhagic eruption. Clinically the attack resembles one of haemorrhagic small-pox.

Complications.—The most important complication is bronchopneumonia, which occurs in 10 to 20% of cases in epidemics and is often the apparent cause of death. Thrombosis of the femoral vein is not uncommon. Arterial thrombosis occurs in 1 to 5% of cases; it may cause loss of the toes or even of one or both feet. Secondary streptococcal infections are fairly common; otitis media has been reported in as many as 10% of cases in severe epidemics, parotitis in 2 to 4%, occasionally with suppuration of the gland. Bed-sores are frequent in severe cases, especially when nursing arrangements are defective.

Sequelae.—In mild cases convalescence is rapid and there are no sequelae, but after severe attacks the patient slowly regains strength and mental alertness. Weakness, slowing of the mental process, tremors of the hands, and partial deafness may persist for some days or weeks. True relapses are practically unknown, but sometimes there is an irregular rise of temperature for some days after the crisis.

Prognosis

The case-fatality rate varies greatly with age; it is almost negligible in children and is seldom more than 5% below the age of 20. It rises slowly till about the age of 40, when it is from 10 to 15%. It then rises somewhat steeply, reaching about 50% at the age of 50. Few patients of 60 and over recover. These figures refer to severe epidemics, but the risk to life always depends largely on the age of the patient. Persons debilitated by starvation bear the disease badly, and the virulence of the infection is a most important factor. Deaths are far more numerous in severe epidemics occurring in half-starved and crowded communities composed chiefly of adults: in such conditions the death rate may be as high as 40 or even 50%. In outbreaks in endemic areas the average rate may be as low as 5 to 10% if all the mild cases are taken into account. Unfavourable features in individual cases are early onset of delirium or coma, haemorrhagic rash or other haemorrhages, leucocytosis in excess of 20,000, bronchopneumonia, and thrombosis of the large veins.

(*The concluding part will appear in our next issue.*)

POST-WAR HOSPITAL SERVICES

By arrangement with the Minister of Health the Nuffield Provincial Hospitals Trust has appointed Prof. J. A. Ryle and Dr. A. E. Quine to carry out a survey of hospital services in the North-East of England (Northumberland, Durham, and Cleveland). This will be conducted on the same lines as the surveys now being carried out by officers appointed by the Minister of Health in the London area and in the North-West. This is part of an arrangement under which the Nuffield Trust, with the concurrence of the County Councils Association, the Association of Municipal Corporations, and the British Hospitals Association, has agreed to assist the Ministry by organizing surveys of hospital services in various parts of the country. The areas to be surveyed and the officers to be appointed will be agreed between the Minister and the Trust. The object is to obtain expert advice on the hospital resources and needs of the areas so as to provide a factual basis on which the Government's post-war hospital policy, which was announced by the Minister of Health in the House of Commons on Oct. 9, 1941, can be worked out. The policy, briefly, is to place a duty on the major local authorities, in collaboration with voluntary bodies, to provide a service which will ensure that "appropriate treatment will be readily available to every person in need of it."

Prof. J. C. Drummond, D.Sc., Scientific Adviser to the Ministry of Food, will deliver the Harben Lectures for 1942 on "Problems of Wartime Nutrition" at the Royal Institute of Public Health and Hygiene, 28, Portland Place, W., on Mon., Tues., and Wed., Oct. 26, 27, and 28, at 3 p.m. In his first lecture he will discuss "The Background to the Study of Nutrition in Wartime"; in the second "Deficiency Conditions to be guarded against in Wartime"; and in the third "Measures taken to maintain a Good Nutritional Condition of the People in Wartime." Admission to the lectures is free, and seats may be reserved on application to the acting secretary of the institute.

WOMAN-POWER AND MATERNITY

The Minister of Health, who presided over the National Conference on Maternity and Child Welfare which was held recently at the B.M.A. House, London, said that the confinements which have taken place in the emergency maternity homes set up under the evacuation scheme number 57,000, and additional homes are kept in reserve in case of need. Only normal cases are attended in these homes, but each home is linked with a hospital for abnormal cases, and the service of obstetric specialists is available if required. At more than 60 hostels women may spend a period before entering a maternity home and again after leaving it. The Minister appealed for women to take up midwifery or to return to it if already qualified. Although there are 65,000 registered midwives, only 15,000 notified their intention to practise last year. In the later proceedings of the Conference the question of the pregnant woman in industry loomed large. There appeared to be general agreement that the armed Forces are not the place for expectant mothers or for mothers with very small children. It is the rule that expectant mothers must leave the Services as soon as possible after the third month of pregnancy. If their record has been satisfactory their certificate is endorsed "suitable for re-enrolment," but no woman is actually enrolled or re-enrolled until 6 months after confinement, and even then it is thought better, if she must be employed, that she should take a civil job rather than re-enter one of the Services.

The question of the pregnant woman in industry is much less easy of solution. Several of those who addressed the Conference spoke of the difficulty of inducing the pregnant woman to report her pregnancy. She is apt to think that there is no reason why her work at the factory should be suspended during the early part of the period, and, of course, the factory doctor cannot inform the management of a woman's pregnancy without her consent. It is also true that most ordinary factory jobs can be done by women in the early stages of pregnancy, but if the work involves the handling of lead or mercury, with the risk of industrial poisoning, or requires the woman to carry heavy weights or to climb heights, pregnancy even in the early stages should be a bar. Pregnant women also should not be allowed on night shifts. Otherwise the length of time the pregnant woman remains at work depends upon her economic conditions and the amount of consideration she is fortunate enough to receive. Dr. Margaret White, who addressed the Conference on this subject, said that in her experience most women worked up to the end of the seventh month. It is worth recalling what Germany and Japan did in this respect, at all events before the war. In Germany no employer was allowed to dismiss a woman 6 weeks before or 6 weeks after her confinement. Time off for breast-feeding and rooms for nursing mothers were provided. The law also ordained less tiring work to be given to pregnant women. In Japan employers were not allowed to let women continue at work for 4 weeks before or 6 weeks after their confinement, and for the time lost a woman received up to 60% of her wages. In this country there is no legislation safeguarding the pregnant woman, probably because female industrial labour has not been so common here as in some other countries. Dr. Letitia Fairfield told the Conference that in her experience the gynaecological disabilities encountered among women in the Services were not nearly so many as were supposed. Any major troubles—fortunately rare—were dealt with at Service or E.M.S. hospitals under specialists, while minor disabilities such as dysmenorrhoea or menopausal conditions were treated either by medical officers in the Service (of whom in the R.A.M.C. and the R.A.F. Medical Service a considerable number are women) or by selected specialists at the hospitals. Women's Services, Dr. Fairfield thought, were well cared for in these respects, but in organizing arrangements for her own Service she had been impressed by the need for better provision for dealing with minor gynaecological conditions among civilian women.

RECENT NUTRITION STUDIES

The report of the Governing Body of the Lister Institute for 1942 is a brief survey of the scientific work done during the year. Special interest attaches to the work of the Division of Nutrition, which is located at Cambridge. Here Dr. Harriette Chick and others have been investigating the biological value of the proteins contained in wheat flours, more especially in national wheatmeal (85%), which is milled to contain as much as possible of the aleurone layer and embryo (or germ) of the grain, and as little as possible of the bran. The biological value of the mixture of proteins in national wheatmeal (as judged by experiments on young rats, taking the weight increase per gramme of protein ingested) was found to be about 15% higher, and that of the proteins in wholemeal (100%) about 20% higher, than that of the proteins of white flour (73 to 75%). The digestibility of the protein in the three types of flour was found to be rather lower in national wheatmeal and in wholemeal, but this is more than compensated for by the higher biological value of their proteins.

Some work has also been done on B_2 vitamins in different types of flour. The highest concentration of riboflavin was found in the germ; that of "middlings" and bran was intermediate; and that of white flour (endosperm) lowest. The contents in white, national wheatmeal, and wholemeal flours were in the order of 1 : 3 : 4. The amount of riboflavin present in wholemeal and national wheatmeal is only about one-half or one-quarter that present in such foods as meat, milk, and eggs, but breads made from these flours may provide an important source of this vitamin, owing to the relatively large amount of bread that is eaten. In its content of B vitamins, as in the biological value of its proteins, national wheatmeal has been found intermediate between wholemeal and white flours, though nearer to the former.

An interesting experiment has been made with dried yeast as a supplement to milk in a rural school community. The dried yeast was prepared from cultivated *Torula utilis* and was well tolerated, digestive disturbances being reported in only three cases. During ten weeks 79 children received, with the school milk, a biscuit daily for five days containing 10 grammes of the cultivated dried yeast, and an equal number received a similar biscuit containing no yeast. The children who received the yeast showed an average weight increase of 1.7 lb., while the control group showed only 1.2 lb. A smaller number of children completed a five-months trial during which the increase in weight of those who received the yeast biscuit was 4.4 lb., while those in the control group showed an average increase of only 3.1 lb.

The influence of intermittent consumption of vitamin C on the development of scurvy has also been studied, and on the basis of experiments on guinea-pigs the conclusion is drawn that in the case of a man a quantity of the order of 100 mg. of ascorbic acid consumed at intervals of several days or even weeks would offer protection against scurvy. This consideration has a bearing on the consumption of vitamin C during winter and early spring, when the urban population has largely to depend on the potato for a continuous but moderate supply of vitamin C. The additional occasional intake of high quantities of ascorbic acid present in those vegetables and fruit which are rich in it acts, in all probability, as a safeguard if and when the consumption of vitamin C through the medium of the potato is not quite adequate.

In addition to these nutrition studies the workers under the auspices of the Institute have been engaged in various serological, biochemical, and endocrinological investigations. Two only can be mentioned here. The technique of typing paratyphoid B bacilli with the Vi bacteriophage has been developed and is being successfully applied in the epidemiological investigation of outbreaks of the disease. In the endocrinological field the effects of male and female sex hormones and their co-operative activity with thyroid and adrenal cortical hormones have been studied, and a study has also been made on the effect of ageing on the weights of endocrine and certain other vital organs.

Reports of Societies

DEFICIENCY DISEASES

The third scientific meeting of the Scottish Group of the Nutrition Society was held at Gleneagles, Perthshire, on August 26, when papers were read on the signs and symptoms of deficiency diseases.

Vitamin B

Prof. V. P. Sydenstricker (U.S.A.), describing the clinical patterns associated with deficiency of the B group of vitamins, pointed out that the requirements for certain of the B group of vitamins depended on the composition of the diet, and that synergistic reactions probably further conditioned the requirements. Vague malaise, weakness, lassitude, nervous irritability, mild depression, muscle pains, anorexia, and consciousness of disturbed gastro-intestinal motility were early symptoms in all group B deficiencies. Later, physical signs developed into fairly definite patterns. All symptoms and signs resulting from dysfunction or degenerative changes of the peripheral nerves and heart were attributed to thiamine deficiency. Certain dermatoses and lesions of the mucous membranes and symptoms referable to the cerebral cortex and mid-brain were thought to depend on depletion of nicotinic acid. Other changes in the skin and mucosae and a variety of disorders of the visual apparatus responded to treatment with riboflavin. In addition to these there were certain dermatoses and ocular disturbances which responded only to treatment with the entire B group. The lecture was illustrated by an excellent collection of coloured lantern slides.

Dr. John Yudkin (Cambridge) reviewed the diagnostic criteria of vitamin deficiency in relation to recognized diseases of unknown aetiology and obscure signs and symptoms. He pointed out that the available tests could be divided into those which demonstrated the existence of deficiency and those which showed that deficiency was the cause of the condition. There were four stages in diagnosis: (*a*) indirect evidence of deficiency, (*b*) direct evidence of deficiency, (*c*) the presence of signs to be expected in deficiency, and (*d*) the cure of the condition by correction of the deficiency.

Vitamin A

Dr. J. R. Mutch (Aberdeen) observed that, although vitamin A appeared to be related to the regeneration of the visual purple, neither the extent nor the rate of dark-adaptation, in his studies, bore any close relation to the vitamin A content of the diet. Since the introduction of wartime restrictions on diet there had been no increase in the amount of night blindness, while chronic blepharo-conjunctivitis and corneal ulceration had decreased in frequency. On the other hand, more infants had shown severe photophobia, which readily cleared up on improvement of feeding and treatment with cod-liver oil and ultra-violet light. Mr. J. Gerrie (Aberdeen) described the value of vitamin A in the treatment of nasal sinusitis of children, a condition which seemed to be increasing at present. The older treatment of weekly antral lavage was unsatisfactory, for in 60% of the cases suppuration recurred after the condition had apparently cleared up. Vitamin A given to cases with suppuration did not seem to influence the infective process, but appeared to be effective in the pre-suppurative stage. A number of non-suppurative cases in which the typical thickening of the antral lining had been confirmed by *x*-ray examination were given vitamin A by mouth or by intramuscular injection, and after one to six months, only about 20% showed suppuration, while 80% of a group of similar control cases treated without vitamin went on to suppuration.

Vitamin D

Prof. Noah Morris (Glasgow), discussing vitamin D deficiency, said that the classical type of rickets with its marked skeletal deformities had almost entirely disappeared in this country, but had left in its place a form of disease which was possibly more dangerous because it was not obvious. Formerly, the earliest manifestations of rickets were thought to appear about the fifth month, but now it was known that rickets might occur in the foetus if the mother was suffering from calcium and vitamin D starvation. He pointed out that while osteomalacia was most commonly associated with pregnancy and lactation, it might also be produced where there was insufficient intake or poor absorption of lime. The non-pregnancy type might often involve the spine alone and was apt to be diagnosed as rheumatism. Tetany might occur, and there was often weakness and stiffness, especially in the adductor muscles of the thighs.

Other Deficiencies

Dr. A. Lyall (Aberdeen), in a paper on calcium and phosphorus deficiency and hypoproteinaemia, pointed out that primary nutritional disturbances of these types were rare. Nutritional hypoproteinaemia was infrequent, but might be associated with anorexia or pregnancy and sometimes with imbalance of chloride and fluid. Prof. L. S. P. Davidson (Edinburgh) reported an investigation he had carried out in Edinburgh on the haemoglobin values in infants, children, and pregnant women, and compared the results with those found in a similar investigation in Aberdeen a few years ago. Prof. H. Dryerre (Edinburgh) gave an interesting lecture on deficiency diseases encountered in veterinary practice.

Correspondence

The Purpuric Type of Cerebrospinal Fever

Sir,—I was most interested to read Dr. I. S. Fox's medical memorandum on fulminating purpura and adrenal haemorrhage (Aug. 22, p. 218), and in particular his comment, in which he states that the accepted view appears to be that these cases "are due to a massive bacteriaemia, and Maclagan and Cooke (1916) suggest a selective action by the meningococcus."

In the *Journal* in June, 1907, I described fulminating cases of cerebrospinal fever with purpura, and the purpura in one case was so extensive that the portion of the body covered with large purpuric blotches was greater than the rest of the body. In this case there was practically no neck rigidity and Kernig's sign was absent. The meningococcus was recovered from the spinal fluid and the patient (a child) died in 22 hours from the onset. This case was seen by me at Purdysburn Fever Hospital, Belfast, where I saw about 350 cases of the disease (1906-8). Purpuric rashes were more common in the earlier stages of the epidemic, being present in 24 of the first 75 cases seen by me.

That there *is* a purpuric type of the disease I have no doubt; and in an article in the *Practitioner* for June, 1915, this type of the disease was mentioned and described by me; in this article one of my conclusions regarding cerebrospinal fever was that acute toxaemia may be caused by meningococci, and that patients suffering from acute toxaemia during an epidemic of cerebrospinal fever should be bacteriologically examined to see if meningococci were present.

At the post-mortem examination of purpuric cases in the epidemic, in addition to the skin condition, haemorrhages were observed on the peritoneal surfaces of the intestines, bladder, kidneys (including the suprarenals), on the heart, and occasionally the pleura. In the abdomen mesenteric glands were very frequently found enlarged and inflamed and the Peyer's patches and solitary follicles affected. In no cases seen post mortem were signs of disease found in the brain and meninges without intestinal involvement being noted, though intestinal signs were observed without any indication of disease in the brain and meninges. These findings, along with the fact that toxaemic cases without cerebrospinal fever had been observed, prompted the suggestion that the title "cerebrospinal" applied to the disease was misleading, and they also suggested the possibility of the intestinal tract being one of the portals of entry of the meningococcus, for in post-mortem examination of some fulminating cases no meningeal signs were evident.

Readers are referred to the articles mentioned. That in the *Practitioner* contains detailed observations regarding several hundred cases of cerebrospinal fever and a note on what I believe was the first case of cerebrospinal fever to receive treatment by Flexner's serum on this side of the Atlantic. I have still in my possession one of the original vials of this serum, unopened, taken from Flexner's original and famous horse.—I am, etc.,

Glossop ERNEST H. M. MILLIGAN.

Lister Technique for Emergency Surgery

SIR,—I agree with Prof. R. J. Willan (Sept. 5, p. 291) that the revival of the Lister technique would be good for emergency operations, but I would add—for all accidents. There seems to be something wrong with the technique of aseptic surgery, judging by some articles in the *Journal* recently on hospital infection of operation wounds. My experience of the Lister technique dates back to the 80's of last century when I was a student under, and afterwards H.S. to, the late Sir Hector C. Cameron, Lister's assistant when the latter was experimenting with antiseptics. During that time I never saw an operation wound suppurate, and we had no stitch abscesses, which seem to be quite common to-day. Accidents did better than they do now. I remember three cases in particular: a compound comminuted fracture of both bones of the forearm with a wound opening into the carpo-metacarpal joint of the thumb; a compound dislocation at the knee with the trochanter protruding through the skin and covered with mud and horse-dung; and a scalp wound extending from behind one ear, over the vertex to behind the other. All these healed without any suppuration.

One of the most important things in Lister's technique, according to a French surgeon, was his "extreme and minute care in dressing wounds." In this my chief copied Lister; for those wounds he did not dress himself he allowed no one but his H.S. to dress. In another hospital where I was H.S. the technique was supposed to be "antiseptic," but the regular routine was for one nurse to go in front of the surgeon to undo the dressings and another to do them up afterwards. Needless to say that nearly every wound suppurated.

Recently, as examiner for an accident insurance company, I have been astonished at the number of septic wounds I have seen. Perhaps the present-day teaching that antiseptics "soil" wounds has something to do with it. When I told a young lady doctor recently how Lister used to pour crude carbolic acid into compound fractures, she exclaimed: "That would cause gangrene; we were taught never to use carbolic acid because it would cause gangrene." Here is a conundrum. Lister saved his patients by using carbolic acid seventy years ago, and to-day it causes gangrene. Why? The crude carbolic was probably about 5% of pure phenol.—I am, etc.,

Birmingham ROBERT ANDERSON.

Group Psychotherapy

SIR,—The most striking feature of Dr. Maxwell Jones's interesting article (Sept. 5, p. 276) is its emphasis upon the low morale so blatantly displayed by present-day "neurotics." During the last war mental conflict was mainly between repressed self-preservation urges and the conscious ideals of courage and "doing-one's-bit" creditably. In the interval between the two wars the process of debunking has been carried to such a pitch that a large section of democracy has come to regard the idea of self-sacrifice as ridiculous if not hypocritical. A reversal thus apparently has taken place, and it is now the moral and herd instinct tendencies which are repressed, while the conscious self-centred urges are shamelessly acclaimed. Conversation with shopkeepers and managers of multiple stores has revealed to me, in a way direct contact failed to do, the prevalent ignorance as to what is involved in this war. I gathered from the above sources of information that any difficulty in getting wished-for commodities is frequently met by their clients with the remark, "We should be as well off under Hitler." No wonder that so many seek to "dodge the column." The group of patients reported upon by Dr. Maxwell Jones is peculiarized neither by having "a very circumscribed outlook" nor by being largely preoccupied with its domestic situation, but rather by having a vegetative lability which can be used as a means of escape from responsibility. Even so, these patients are at no pains to hide from themselves or others their dislike for serving their country. In such an atmosphere psychotherapy is indeed "conducted under rather difficult conditions." Dr. Maxwell Jones's triumph is to have realized that what these so-called neurotics need is education. Both the methods he suggests are admirable, but should not be confined to E.M.S. neurosis centres or special clinics.

The question, however, arises as to how far the medical profession is justified in a deliberate attempt to inculcate moral principles. The question might be asked in the House. The psychotherapist in the last war felt himself on safe ground when showing a "shell-shock soldier" that courage was compatible with fear and that the latter should be overcome but not repressed. In this war it has become rather embarrassing to explain to so-called neurotics that courage and self-sacrifice are anything other than avoidable foolishness. Hence the plan for group education, as set out by Dr. Maxwell Jones, is a most promising one.—I am, etc.,

Caldecote. A. E. CARVER.

Circulatory Overloading after Rapid Intravenous Injections

SIR,—It is possible that the most interesting article on circulatory overloading following rapid intravenous injections by Drs. E. P. Sharpey-Schafer and John Wallace (Sept. 12, p. 304) may result in some clinicians belittling the dangers of too rapid infusions in patients who are not "convalescent without cardiovascular disease." The authors do not in any way suggest that the reaction of ill people, possibly actually undergoing an operation, would be similar to that of their experimental subjects; nevertheless there would seem the risk of such being inferred.

Less than two weeks before the publication of this article a patient of mine, aged 46, with a chronic lung abscess, died from pulmonary oedema 2 hours after lobectomy. The operation, which was associated with moderate blood loss, lasted approximately 2¼ hours, during which a pint of normal saline and 3½ pints of blood were given. He was in excellent condition at the end of the operation, but as soon as he was returned to bed became cyanosed, and respirations were "bubbly" as a result of the accumulation of thin, blood-stained, watery fluid in the air passages. In spite of repeated aspiration of this fluid he died 2 hours after the end of the operation. At necropsy the right side of the heart was bloated with blood and the lungs and air passages filled with great quantities of blood-stained oedema fluid.

Instead of a convalescent subject with a normal cardiovascular system we were dealing with a middle-aged man who had suffered the chronic toxic effects of a lung abscess for 12 months, and who was receiving operative trauma at the time of the infusion. Under such conditions the dangers of too rapid intravenous injections are only too real.—I am, etc.,

St Albans. OSWALD S. TUBBS.

Hereditary Factor in Cardiovascular Disease

SIR,—Dr. Edwin Goodall (Sept. 12, p. 322) has raised a most important point, and one urgently requiring attention, when he stresses the importance of studying the hereditary incidence of hypertensive disorders and "replacing impressions by reliable family histories on a uniform basis." The tendency has often been to place the blame for hypertension on mental or physical stress, diet, tobacco, or alcohol, and to neglect the hereditary aspect of this condition.

Weitz, in a most interesting address before the Deutsche Gesellschaft für Kreislaufforschung at Bad Nauheim in 1936,[1] described in great detail his investigations over a lengthy period into the histories of patients suffering from hypertensive disorders—not only their pedigrees, but the details of their personal lives which might be considered likely to influence their blood pressures. His conclusion was that, apart from dietary influences in certain cases, the main causal element was that of heredity. Campbell[2] states that in 30 cases of inherited heart disease associated with arteriosclerosis, obesity, and hyperpiesia, investigated by Ryle and himself, 24 gave a history of the father or mother being also affected, while in 6 cases the parents were unaffected but the sibs of the patients suffered from the same disorder. This would appear to show that, while usually dominant, the condition may also be inherited as a recessive trait.

---

[1] *Verhandl. der Dtsch. Gesellsch. fur Kreislaufforschung*, 1936, 9, 11.

[2] In Blacker's *Chances of Morbid Inheritance*, London, 1934, p. 245.

Allen[3] affirms that heredity is more important than all other factors in the aetiology of arteriosclerosis. He points out on the one hand the individual with healthy forebears, from the cardiovascular point of view, who in spite of severe stresses and strains reaches old age with healthy arteries, and on the other hand the young patient with advanced arteriosclerosis, perhaps associated with diabetes, in whose case the only contributory factor is a poor eugenic background.

For several years I have collected pedigrees of patients with hypertensive disorders, and find in these strong confirmatory evidence for the hereditary causation of the circulatory diseases. One such pedigree, with detailed notes on individual members, I have recently published in the *Eugenics Review*.[4]

I feel most strongly with Dr. Goodall that the whole question of the inheritance of hypertensive disorders is of such immense importance that it merits detailed investigation by as many observers as possible, both in hospitals and in private practice, and the correlation of their findings by geneticists and statisticians.—I am, etc.,

Coningsby, Lincoln. J. W. McFEETERS.

Failure of Splenectomy in Purpura Haemorrhagica

SIR,—I hope your readers will not be unduly influenced by the levity, probably inadvertent, with which Prof. Witts in his paper on ulcers of the leg in purpura haemorrhagica (Sept. 12, p. 309) decides on removal of the spleen. As the platelets numbered only 19,000 and 20,000 respectively, "splenectomy was advised." In one case no benefit was obtained, and in the other an excellent recovery was made. In the later case it is too early to say that this is permanent, for a period of improvement in purpura haemorrhagica is often followed by the recurrence of the disease in all its aspects notwithstanding splenectomy.

It is now some 17 years (*Lancet*, 1925, **1**, 323) since the late G. A. Sutherland and I introduced splenectomy into this island as a treatment for purpura haemorrhagica, and enough experience has been gained to state that splenectomy has a very limited role in the treatment of that condition. In my later experience splenectomy is only justified (1) in severe cases which fail to respond to dietetic and antitoxic measures designed to eradicate foci of infection, and (2) in fulminating cases where death is threatened from exsanguination by external haemorrhage. The temporary benefit seen after splenectomy would appear to be due to the removal of a depot or concentration in the spleen of the factor which has the faculty of increasing the permeability of the capillaries to the extravasation of erythrocytes which manifests itself as purpura and ecchymosis.

When splenectomy was first applied in purpura haemorrhagica it was thought that the condition was due to an essential thrombocytopenia, but further experience does not bear out this theory. Lack of circulating platelets is found in practically all conditions in which purpura is seen—e.g., the specific fevers, diphtheria, nephritis, etc. In these conditions a toxic effect on the capillary wall seems a reasonable pathological explanation, and the scantiness of the circulating platelets may be explained by the numbers immobilized in plugging the lesions in the capillaries. Where the primary condition is not recognized, an essential failure in platelet production is postulated in the term "essential thrombocytopenia," but this is no more than an expression of our ignorance, and there is no evidence whatsoever that it is a disease *sui generis*, as is implied by Prof. Witts in his introduction. Splenectomy does not remove the cause of the loss of circulating platelets except for a brief period in chronic cases. In mild cases I have had successful results by purely medical measures designed to raise the general standard of health.

The failure of splenectomy in purpura haemorrhagica is well illustrated in a post-operative history of some 17 years in all three cases in our original paper. Apart from a brief period of under two years immediately after the operation, during which clinical manifestations were scanty or absent, these patients could and can at any time be diagnosed as victims of purpura haemorrhagica (and of splenectomy). The female histories are almost identical, with menorrhagia, metrorrhagia, epistaxis, purpura, and anaemia. During this period one has undergone an emergency abdominal operation for severe ovarian haemorrhage. (This has also occurred in another case under my care splenectomized at Bradford in 1928.) In recent months the third case in our original communication has given cause for great but unfounded anxiety. She reported herself as pregnant. Despite twenty years' history of haemorrhages and purpura she went to labour and gave birth to a fine boy with a total loss of only 3 oz. of blood notwithstanding a platelet count of only 50,000 per c.mm. throughout the whole gestation. The baby was born with purpura on the tip of his nose and on the palate, and the platelet count was only 40,000 on the 14th day of life: since then no further purpura has occurred and the platelets are normal at 260,000 per c.mm.

I fear I have trespassed beyond the normal confines of a letter, but I think it is important to mitigate the mischief which might be caused when splenectomy is undertaken from a chair of medicine with no higher grounds stated than lack of platelets, a feature which the operation more often than not fails to alter in severe cases. I quite realize that Prof. Witts was experimenting in his two cases, but his reason for the operation is too baldly stated and too casual in its implication to pass unchallenged.—I am, etc.,

London, W.1. BRUCE WILLIAMSON, M.D., F.R.C.P.

Single-handed Anaesthesia and Operation

SIR,—Dr. W. Brian Gough (Sept. 5, p. 295) has raised the question of single-handed operating and anaesthetizing. In the present state of medical public opinion it is bad policy for a doctor to attempt both. Leaving policy on one side for the moment, and regarding merely the facts, we do find that when matters are suitably arranged the patient is his own best anaesthetist, requiring only that amount of help which any person capable of watching or hearing air bubbling through ether is competent to give. That means in practice anybody provided he is not both blind and deaf. It is a well-known fact, though much neglected, that the secret of safe anaesthesia is an open airway. The procedure then for the would-be combined operator and anaesthetist is as follows: (1) get the patient under; (2) introduce a tube into the trachea and fix it and connect up with the suitable apparatus.

It would be tedious to describe this suitable apparatus, but it may be said that it has the following advantages. It is very simple. It is inexpensive (£3 13s. 6d.). It is automatic in action. It is more accurate than the most skilled anaesthetist, for the dose is exactly regulated to the operative procedure by a mechanism that has been perfected over many millions of years—namely, the patient's own respiratory centre. It can be and is generally used with oxygen from a cylinder, but is quite independent of that oxygen. This is a very important point. If the definition of the anaesthetist which afforded a source of never-failing amusement to one of the greatest of living surgeons—namely, "that person who sits at the head of the table more than half asleep while the patient on the table is more than half awake"—has any measure of truth in it, and it has some, then the said anaesthetist may not notice when the oxygen cylinder of a Boyle or a McKesson has run out. In such a case the oversight, even if short-lived, might be fatal. With the apparatus in question it wouldn't matter, for the patient would still be getting as much O_2 as the rest of us. If oxygen from a cylinder is being used, the lungs can be flooded with oxygen in two seconds by merely turning the tap of the oxygen cylinder—a manœuvre which also stops the anaesthetic. By pinching the tube on the exhaust valve 16 times a minute oxygen pressure in the lungs can be varied as required without danger of rupturing the air vesicles. By immersing this same tube in water, pressure in a collapsed lung can be raised to any desired height. Anaesthesia with it is so simple, so safe, so automatic, that one anaesthetist provided with six watchers could quite easily superintend as many operations in a theatre arranged for that number. Ether, $CHCl_3$, gas and O_2, and CO_2 have been given by means of it.

After what I have said it might seem that here at last is the secret of immortality, but this is not so. The human heart, one of the most wonderful things in creation, wears out at last, and occasionally that moment comes when under the influence of an anaesthetic. The apparatus puts the patient in the best possible position to carry on a bit longer. It has one disadvantage—it does not anticipate the wishes of the surgeon but rapidly overtakes them.—I am, etc.,

Manchester. E. FALKNER HILL.

Bee Stings

SIR,—Dr. R. Drummond (Sept. 19, p. 352) need not be surprised. His desperate run may have saved his life, as it is possible that violent exercise after being stung is a prophylactic against anaphylaxis.

A recent personal experience suggests this explanation. On the hottest day of August this year I was attacked by bees near an apiary on Exmoor, and directly afterwards pushed and dragged a bicycle through dense heather for over a mile, a very sweaty job. Except for slight itching, the 10 or 12 stings on face, ears, and scalp caused no symptoms. Yet a few years ago I suffered from severe symptoms of anaphylaxis after half that number of stings, as described in a letter to the *Journal* (Aug. 26, 1939, p. 471) to which Dr. Jex-Blake refers. On this occasion I suggested non-specific sensitization as a possible cause of the reaction, as I had been given injections of immunogen for pneumonia a few weeks previously.

---

[3] *Nelson's Loose-Leaf Living Medicine*, 1924, **4**, 531.
[4] *Eugen. Rev.*, 1941, **33**, 73.

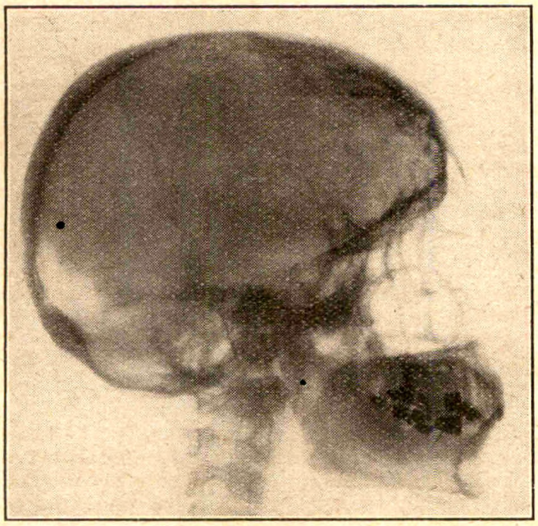
A shrewd old "beeman" once got badly stung looking through a hive of mine. I offered to drive him home, but he refused, saying that he would walk it off and that he would be better for a good sweat. Now sweating usually *accompanies* anaphylactic shock; hence is it not more likely that any good effects of exercise are due either to increased lymph flow or to the presence in the circulation, as the result of muscular activity, of a chemical substance antagonistic to bee venom? Here, perhaps, although in the reverse direction, may be an explanation of the effect of bee venom in the treatment of muscular rheumatism, an effect vaguely attributed to "protein shock."—I am, etc.,

Exeter. R. FORTESCUE-FOULKES.

Hyperostosis Frontalis Interna

SIR,—Dr. C. T. Andrews's interesting publication (Aug. 15, p. 185), and the discussion which followed, prompt me to report a case recently seen by myself which presented, together with the typical radiological appearances of the disease (*vide* photograph), unusual attacks, and I should be grateful for an opinion as to the mechanism of their causation.

The patient, again a woman, 44 years of age, had a fall on the back of her head in March, 1940. Symptoms appeared for the first time three weeks later, five days after a minor gynaecological operation under a general anaesthetic. They consisted of inability to get up owing to severe disturbance of equilibrium (tendency to fall backwards) and a dragging sensation at the back of the head. After rest in bed for two weeks, when pressure and a cramp-like sensation was felt in the occipital and temporal regions of the head, attacks of tinnitus, nausea, vomiting, diarrhoea, cold perspiration, and "deadness" of hands, feet, and nose occurred, which lasted for several hours and recurred at first three times a week. With rest they became gradually less severe and less frequent. During these attacks hyperacuity of hearing and oversensitiveness to light were noticed. Pressure in the head, giddiness, and occasional vomiting persisted until the end of 1941, and impairment of general health, muscular weakness, and ill-defined sensations in the head are still present.



Apart from a definite obesity of the girdle region and the thighs, nothing abnormal was found on clinical examination. Menstruation was regular, but lasted for two and a half days only instead of the customary four days before the present illness. Low body temperature. Blood pressure 130/80. No abnormal constituents in the urine. B.M.R., −18%. Blood-sugar tolerance curves: fasting 90 mg. %, 160 mg. % half an hour, 170 mg. % one hour, 120 mg. % one and a half hours, 80 mg. % two hours after ingestion of 50 g. of glucose. Serum calcium 12 mg. %. Haemoglobin 84%, R.B.C. 4,480,000; blood platelets 313,000; bleeding time 3 minutes; coagulation time 5 minutes; differential leucocyte count: 2% eosinophils, 57% polymorphs, 35% lymphocytes, 5% monocytes. The *x*-ray film of the skull shows hyperostotic changes in the frontal and perhaps in the parietal and sphenoidal bones. The outer table is not involved. The diploe of the entire vault appears thickened. The frontal sinuses are large and there is marked over-pneumatization of the mastoid cells.

As in most cases of hyperostosis frontalis, symptoms are not directly attributable to local pressure of the newly formed bone. The symptomatology of this disease is often so ill defined that it is usually diagnosed as hysteria. A frequent occurrence is that symptoms appear only after cranial injury (cf. Knies and Le Fever, *Ann. intern. Med.*, 1941, **14**, 1858). An interesting question which has arisen in the present case and which may apply to similar cases is whether an accident insurance is liable to pay compensation for the post-traumatic impairment of health.

Dr. J. MacKay Crawford (Aug. 29, p. 261) is right in pointing out that Dr. Andrews's case has a *lowered* glucose tolerance (the glucose tolerance *curve* being abnormally high).

As to the causation of the condition, most authors regard, contrary to Prof. Henry Cohen's view (Sept. 5, p. 292), a dyspituitarism as one of the causative factors. The reason for this is that anterior pituitary function is intimately linked with cranial architecture, so much so that cranial dysplasia can be regarded as a pathognomonic manifestation of pituitary dysfunction. Lack of pneumatization, thin external and internal tables, and sclerosed diploe are signs of primary hypoantuitarism, while over-pneumatization, expansion, and increased vascularization of the diploe occur with primary hyperfunction of the anterior lobe (cf. Mortimer, Levene, and Rowe, *Radiology*, 1937, **29**, 135). Secondary functional deficiency of the anterior lobe manifests itself in sclerosis of the diploe either in a normal or over-pneumatized skull according to the primary state of pituitary function. Hyperostosis frontalis interna can probably be regarded as a special form of this cranial dysplasia.

Dr. Andrews has reviewed the literature and stressed the possible relation between the anterior pituitary lobe and the parathyroid glands. The cranial changes in acromegaly and pituitary dwarfism point to the significance of the eosinophil cells of the anterior pituitary lobe (growth-promoting factor) for cranial development, and Hemphill and Stengel (*J. ment. Sci.*, 1940, **86**, 341) have found an eosinophil adenoma in one case of hyperostosis frontalis interna.—I am, etc.,

London, W.1. H. UCKO.

Sunlight Eruptions after Medication for Gonorrhoea

SIR,—Referring to the article by Capts. R. G. Park and W. M. Platts (Sept. 12, p. 308) on sunlight eruptions in patients with gonorrhoea treated with sulphonamides, the following observations are probably worth mention. In Vienna in the late 'twenties intravenous injection of acridine and its derivates had been widely used for the treatment of gonorrhoea. A considerable percentage of patients treated in that way showed photosensitivity—namely, an erythema on the parts exposed to the sun, followed by a deep dark pigmentation. Occasionally the pigmentation affected the mucous membrane of the lips. Following the recommendation of French dermatologists, resorcin tablets (0.25 gramme) were given after the injection as a preventive with good results.—I am, etc.,

Bacup. A. FESSLER.

"Constipation" in Breast-fed Babies

SIR,—Prof. Charles McNeil in his alphabet of breast-feeding (Sept. 5, p. 271) perpetuates an old error. He clearly believes that a breast-fed baby ought to have a daily bowel action. Under the heading of "constipation" he writes: "One type of constipation fairly common in breast-fed babies is of special character and seldom described in books. There is no bowel movement for two or three days, and then the passage of a large soft healthy motion. General health and digestion are excellent. The cause is anal spasm . . . the remedy is to pass the little finger covered with vaseline into the anal canal. . . ." Thus an imaginary pathology ("spasm") is invented to explain a non-existent disease ("constipation").

Large numbers of perfectly healthy breast-fed babies will only have a bowel action every two, or three, or even four days. As Prof. McNeil says, these babies thrive and their stools, though infrequent, are soft and healthy. Why then need we suppose that there is anything the matter? Why must they conform to our adult standard of a daily action? Our duty in these cases is to allay maternal anxiety and prevent the giving of aperients. I repeat, there is nothing whatever the matter with these babies, and they should be left alone. The regular daily habit will establish itself later on.—I am, etc.,

Crowthorne, Berks. E. F. Chapman.

Nomenclature of Night Blindness

Sir,—I hope you will permit me to comment as briefly as possible on the very interesting discussion between Mr. Francis E. Preston and Dr. J. Price Williams on this subject.

In vol. 14, p. 776, of Kuhn's edition of Galen these two sentences occur: "Amaurosis—a complete obstruction of vision without visible cause. To suffer from nyctalopia means that the patients see somewhat dimly (amauroteron) by day, more clearly in twilight, and at night more clearly still: or, conversely, poorly by day, and in the evening or at night not at all." This passage seems to be the source of the definitions of hemeralopia, nyctalopia, and amaurosis quoted by Mr. Preston, though it will be noted that, whereas Galen describes amaurosis as a complete obstruction of vision, Neame and Williamson-Noble call it a serious defect of vision. Nyctalopia and hemeralopia we must, I think, abandon. If even for Galen nyctalopia means both to see better by night than by day and to see better by day than by night, and if hemeralopia is equally paradoxical, then there is no help in them.

As for differentiating complete from partial blindness, the trouble is that in Greek as in English "blindness," "deafness," "baldness," and the like are not absolute terms, except by further qualification, or by convention, as in Galen's definition of amaurosis, they permit of gradations. A deaf man may be anything from hard of hearing to as deaf as a post; a blind man may be as blind as a bat or an owl: he may be gravel-blind or stone-blind; a bald man as bald as a coot or as a billiard ball. "Amauros" originally meant "dim," "obscure," and "amaurosis" meant "dimness of sight." It is, however, probable that in ancient Greek the meaning of the word tended to move in the direction of total loss of vision, just as the classical "amauros" (dim) has become in modern Greek "mauros" (black); though we see that even after defining "amaurosis" as complete obstruction of vision Galen in the next breath speaks of patients seeing "somewhat dimly" (amauroteron) by day. At any rate in modern medical terminology it is fair to say that "amaurosis" is the strongest candidate for the representation of total blindness from any cause. "Amauria" and "amauroma" are also, it is true, genuine though rare words, but it seems illogical and arbitrary to take three words of the same root and make "amaurosis" mean total blindness without visible cause, "amauria" total blindness, and "amauroma" partial blindness. For partial vision we have already the adequate and exact term "amblyopia"—vision which has lost its edge and is blunted but which still exists.

With regard to Dr. Price Williams's criticism that the termination "oma" denotes something concrete or objective, this is usually but not invariably true, whether in ancient Greek or modern terminology. This very word "amauroma," for example, occurs, I see, in a medical writer of the 3rd century B.C. with the meaning "dullness of vision"; and the modern glaucoma, whatever its aetiology, is rather a pathological process than a concrete object, though it must be admitted that to Galen a glaucoma meant an actual cataract.

Regarding Mr. Preston's objection to "amaurosis," when Galen defined "amaurosis" as complete loss of vision without visible cause he had just finished enumerating a list of gross ocular defects—wounds, ulceration, leukoma, staphyloma, scarring, etc., all obvious causes of total blindness. That still left him with a good deal of blindness to account for—optic atrophies, detached retina, embolism of the central artery, and so on. The first class he would designate by the name of the primary cause; the second he had to lump under the common denomination of "amaurosis." But, as Mr. Preston hints in his second letter, the ophthalmoscope has been invented since Galen's time, and there can now be few cases of complete or partial blindness without visible or at any rate ascertainable cause. "Amaurosis," in fact, in the Galenic sense has become an unnecessary term, and "nyctalopia" and "hemeralopia" are in process of becoming tobacco amblyopia or retinitis pigmentosa or vitamin A deficiency.

I suggest that we use "amaurosis" to mean complete loss of vision, without qualification of cause, and "amblyopia" to mean partial loss of vision. "Nyctamaurosis" would then mean complete loss of vision at night, if we ever needed such a term, and "nyctamblyopia" partial loss at night. Functional and orgainic are terms somewhat blown upon at the moment, but I would regard such a condition as retinitis pigmentosa as an organic, and vitamin A deficiency as a functional, nyctamblyopia.

When I saw Mr. Preston's original communication I wondered whether the resources of the English language were adequate to the need and thought of "night blindness" and "night purblindness," but if the *Shorter Oxford English Dictionary* is correct English is as ambiguous as Greek, for the first meaning of "purblindness" is "total blindness" and the second "partial blindness."—I am, etc.,

Barrow-in-Furness. John Ware.

Loneliness in Infancy

Sir,—Your excellent article on "Loneliness in Infancy" (Sept. 19, p. 345) should do much to draw attention to a line of treatment productive of good results.

Children taken from raided areas into hospital are in need of coddling, friendship, and protection. I know of children who for want of it during such strenuous days have literally turned their faces to the wall. It was not until others, infants and toddlers, behaved in the same way that we began to probe into the reason. Possibly there may be "loneliness in adults," and more than we realize, for we all know the story of the soldier who was so terribly wounded, saying, when his mother came, "Oh, nurse, how like my mother's touch!"—I am, etc.,

Eastbourne. A. H. Macdonald.

The Guild Spirit

Sir,—The late G. K. Chesterton, that profound philosopher-historian, would have been horrified and grieved at the idea of a State Medical Service. Chesterton always upheld the guild method, as opposed to wage slavery, whether under State capitalism or private capitalism. Every doctor to-day ought to read his essay "On the Bad Word for Guild" in his book of essays called *All is Grist*, first published in 1931. In this essay he specifically quotes the medical profession, saying:

> "Now the Guild method is no more mediaeval than it is modern, in so far as it is a principle apart from time. The best proof is that it does still exist in a practical profession with which we are all acquainted. The doctor, the ordinary general practitioner, whom most of us know and to whom many of us owe our lives, is a typical example of the member of a Guild. He is not a Socialist official; he is not a State servant; he is an example of private enterprise. That is to say, he owns his own lancet and stethoscope; he has to buy his own practice; he does in a certain degree compete with the men of his own trade. But he is forbidden to compete with them by certain methods; he is forbidden to drive another doctor out of his practice by certain expedients of self-assertion or self-advertisement; he has to observe towards his fellow-doctor a certain respect and consideration. He has to do this because he has joined a Guild or confraternity, which exists for the maintenance of the members of his profession as a whole. Its definite and deliberate policy is to keep all the doctors in existence, as far as possible, and *prevent* one of them destroying all the rest. Once it is admitted that a man may use any methods of advancement and advertisement, the chances are that about twenty honest doctors will be swallowed up by one quack. We know this is what has happened in journalism and in commerce, and in any number of other things."

Surely half the discontent in the profession to-day comes from the fact that doctors are confusing their quarrels with each other (mostly due to injured vanity) into quarrelling with the system under which they work. And every secretary of a Division must know that if only doctors would attend Division meetings more often and honestly air their views and grievances, instead of sitting on their bottoms telling all and sundry how lousy the B.M.A. is, the world would be a happier place.—I am, etc.,

William McKim,
Coxwold, York. Hon. Sec., York Division.

The Profession Votes

Sir,—With its usual lack of logic and its usual perversity our profession has voted for changes in our organization which will have the worst features of State medicine and private practice. Our fundamental error in sounding medical opinion now about changes in our profession is that the men in the Services, who have not been consulted, are men whose practices are melting away or who have never had practices. They will, therefore, be in the position after the war of "have nots," and will hold opposite views to us who are "haves."

No attempt has been made to divert more medical man-power into industrial districts and away from fashionable watering-places; indeed, the size of the staff of our provincial hospitals is decided, not by the district's needs, but by the capacity of the wealthy patients to support the consultants. The anomaly of half the profession overworking and the other half (in peace-time) underworking has not been corrected. While we have signified our willingness to attend our rich patients for 9s. 9d. a year, or whatever we can screw out of the Government, thereby voting for a complete State Medical Service, we have not got rid of the inefficiency due to cut-throat competition. We have voted for group practice, but not that imposed by the Government. Anyone who has, as I have, tried to get a town full of "rugged individualists" to combine will know that group practice will never come of itself. My Division voted for health centres, but not ones provided by the Government, hoping that a health centre would grow out of the ground, for I am sure that we doctors will never pay the £1,000 or £2,000 per head which such a centre will cost. In fact, the mess for which our profession has voted is truly laughable. But the first election after the war will give us a Socialist Government, which, if it continues in power for 5 years, will nationalize us whether we want it or not.—I am, etc.,

Colchester. M. E. LAMPARD.

Medical Planning

Sir,—I, like most other medical men, have followed the discussion which has been going on for some time in the *Journal* on the subject of proposed changes in the conduct of medical practice in this country. It would be interesting if the B.M.A. could publish at this stage a history of the rise of this demand for change, which seems to have descended upon the profession with some suddenness, despite the many preoccupations its members have at the present time. Assuming that changes have to take place, let me say at once that I am in favour of a State Medical Service and not of adaptations of the present system or intermediate schemes which dwell in no man's land. I believe that should a plan of the latter type be adopted it will simply be a matter of time before the full State service comes along.

In my view a State Medical Service means precisely what the words imply. All medical practice outside institutions would be included in it, and all hospitals of whatever type would also be in it. There would be one portal of entry into the profession, implying the abolition of the various types of examination which at present give access to the *Medical Register*. So far as possible, a period of six—preferably twelve—months would be spent by the newly qualified man in hospital posts. Thereafter he would be posted as assistant to a health centre (it seems that the idea of health centres has made a universal appeal to the profession). After a year he would be eligible for promotion to the position of principal at the same or a similar centre. His work would continue along these lines, in many cases, for the rest of his professional career, punctuated with periods of postgraduate study. In other cases within a variable period—say four years as a minimum and eight years as a maximum—the doctor would be entitled to apply for junior posts in various types of hospital or special practice—e.g., public health. Thus a man wishing to take up work in tuberculosis would, if his application was successful, be posted to a tuberculosis dispensary or sanatorium, and similarly for pure medicine, surgery, or any of the specialties. If after a probationary period he showed aptitude for the special work, his appointment to that type of work would be confirmed and he would thereafter gradually accumulate the experience and skill which would enable him to become what is called, at the present time, a "consultant" or "specialist."

It will be observed that under this scheme it would be impossible for any medical man to take up a specialty before having served for a period varying from four to eight years in the practice of general medicine. This is a reform which is urgently necessary in this country.

The plan is essentially democratic in principle for the reason that all entrants to the profession would have a relatively equal chance of advancement (when I use the word "advancement" I am not thinking in terms of finance at all). The Cabinet Minister has ordinarily to serve an apprenticeship as a back bencher. The most famous occupant of a university chair would have served his time in a health centre as a general practitioner. Who will say that this method of professional progression would not be an incalculable gain? Some might go further and say that just as a specialist in the Navy has, between his spells of employment in his own sphere, to return for a period to sea, so the specialists envisaged in this scheme might be returned for short periods to general practice in a health centre. Such a scheme would go far to prevent the growth of the caste system in medicine, and would help on the one hand to keep up the standard of general practice, and on the other to induce a proper feeling of humility in the consultant mind, a feeling always induced by contact with the problems of general practice.

I am aware that in this scheme, as in any other, there are many points of detail to be thrashed out; but in its broad essentials it possesses a unity and simplicity which may commend itself to many who are able to consider the problem in a detached way—a way incidentally not given to many.—I am, etc.,

Wrexham. D. LIVINGSTONE POW, F.R.C.S.Ed.

Goodwill and Compensation

Sir,—Dr. C. G. Jones (Sept. 5, p. 293), in that part of his letter dealing with "goodwill," compensation, and relative sacrifices, gives us the false analogy *par excellence*. The purpose of this war is now reasonably clear, but it has not yet emerged that those who make the supreme sacrifice do so in the cause of State (or any other) medical service. Nor do they give their lives to provide a world made safe for injustice. In other words, Dr. Jones's argument condoning non-compensation, though it will unquestionably be approved by the lay bodies who will determine these matters, is entirely irrelevant.

The question of compensation for loss of "goodwill" can be dealt with, in principle, fairly simply. "Goodwill" is not only by far the most expensive but the most indispensable asset of the general practitioner. It is, in fact, a *sine qua non*, and if it is to have a cash value that value is presumably substantial. Assessment of "goodwill" as a cash value is either right or wrong. If right, then it appears that the destruction of such an asset by authority in any change-over to a State Medical Service should carry just compensation. If wrong, then it appears that the large body of practitioners who have had to pay heavily to acquire a practice have already been very seriously victimized, if not actually defrauded. In this case the community, having approved and encouraged this business for so long, cannot in plain justice destroy without compensation this fundamental asset. Communal cynicism of such flagrancy as that may or may not have been proper to the pre-war period, but in the name of all that we are fighting for let us kill it at, or better still before, its rebirth into the post-war world.—I am, etc.,

Birmingham. W. SUMMERS.

Salaried Service and Competition

Sir,—I think a majority of doctors will agree with Dr. Lennox Johnston's observations (Sept. 5, p. 294). The unhealthy competition in general practice from considerations of personal gain, local prestige, and fears for an uncertain future should be eliminated. The time and energy expended in over-visiting and over-prescribing—admitted by doctors, patients, and pharmacists—could be usefully diverted to real medical and scientific work. "Free choice" savours of a pandering to the whims and idiosyncrasies of doctors and patients, and would, in my opinion, perpetuate the humbugging element now present in practice.—I am, etc.,

Luton. W. D. HOSKINS.

A Nutrition Council

SIR,—Your admirable leader on this subject (Sept. 26, p. 370) suggests some psychological difficulties which—as we medical people are all psychologists nowadays—might be discussed in a medical journal. You write: "It seems obvious that the work should not be undertaken by any Government Department which has as its head a Minister who, whatever else he is, is first and foremost a politician." That would not only seem, but be, obvious in a rational world; but we do not live in a rational world. Those of us who were brought up on Walter Bagehot's *English Constitution* recall his wise remark: "The experiment of conducting the administration of a public department by an independent unsheltered authority has often been tried, and always failed." Any department the success or failure of which has not the potentiality of making or breaking a political career will have little influence on administration. If we try to circumvent this difficulty by setting up a council of elderly notables one has a different difficulty. The publicity value of scientific skill or administrative skill within the field of nutrition is very small. The council, to have prestige value, must be "eminent"; its real work must be done by the obscurely competent. But if the members are eminent they would lose no face by *nominally* subordinate association with, say, the Medical Research Council. Only those with little dignity stand on it. There would be a clear saving in administrative expenditure; each new official organization means new staff, new offices, new competition.

These seem to me arguments in favour of Viscount Dawson's contention.—I am, etc.,

MAJOR GREENWOOD.

Medico-Legal

A FATAL ANAESTHETIC

Anaesthetists do not often appear in court to answer charges of negligence, and so their legal pitfalls are not illuminated by much case law. A recent judgment[1] of Mr. Justice Lewis at Winchester is therefore particularly valuable. A married woman had to undergo an operation for the removal of gallstones. The surgeon and the anaesthetist decided in consultation that anaesthesia should be induced by an epidural nerve block with decicaine. This was the first occasion on which the anaesthetist had used decicaine for this block, but the surgeon had previously used it more than once to produce splanchnic and other blocks. The anaesthetist told a sister that decicaine would be used, and instructed her to prepare the solution. This sister had the highest qualifications, had been in charge of the theatre for six years, and everyone relied on her. She had been in charge on previous occasions when decicaine had been used in the ordinary strength of 0.1%. On this occasion, however, believing that she was carrying out the anaesthetist's oral instructions, she prepared a solution of 1%, and the patient died of the overdose. On behalf of the woman's estate and as a dependant (for he was a cripple), the husband sued the anaesthetist for damages. Defending counsel were instructed by Messrs. Hempsons, Ltd., solicitors to the Medical Defence Union. At the trial the anaesthetist and the sister gave conflicting accounts of his instructions to her. His evidence was: "I said 0.1%, the solution of decicaine the same as Mr. M. [the surgeon] uses for the splanchnic nerve block." The sister, on the other hand, agreed that the anaesthetist spoke of decicaine, and that he said it was the same as Mr. M. used for splanchnic nerve block, but declared he had said 1% and not 0.1%. She added that she had thought 1% was an unusually large dose, but had no doubt that she was carrying out the anaesthetist's instructions. She produced the solution in a bottle, and the evidence again conflicted on how nearly she approached the anaesthetist with the bottle. He was busy preparing the apparatus; the sister said she came to within a yard of him and the doctor said she did not come nearer than three yards; he did not examine the bottle. They agreed that the sister said, "Decicaine; is that right?" and that the anaesthetist replied that it was; the sister, however, said she heard "1% decicaine," and the doctor said he heard "0.1% decicaine."

The learned judge said that the real question was whether the anaesthetist owed a duty to do more than state clearly to a responsible and efficient sister the anaesthetic he required. All who take part in an operation, he said, work as a team. If a sister is inexperienced, it is no doubt right for the surgeon and the anaesthetist to take care to see that she is carrying out, or is competent to carry out, the duties assigned to her; and they might have to do more for themselves in the way of supervision than they would if she were experienced. When, however, they are served by a sister upon whom every reliance can be placed, it is sufficient to say, as the anaesthetist said in this case: "I want the solution such as Mr. M. uses for a particular form of nerve block: splanchnic nerve block." The anaesthetist had given his evidence in such a low voice that the judge could well imagine the sister not hearing distinctly what he said. He could not find that in the circumstances either the anaesthetist or the sister had been negligent; an unfortunate mistake had been made. He therefore gave judgment in favour of the anaesthetist, whose counsel did not ask for costs.

The principle that a surgeon or anaesthetist may in some circumstances rely on a subordinate was recognized by the Court of Appeal in Mahon *v.* Osborne[2]—the "Manchester swab case." A swab was left in a patient's abdomen through a miscount by a nurse: Lord Justice Scott said that the surgeon has to keep in his mind the risk of error by a nurse, but on the other hand he should not be deprived of all support from the count; the jury can find negligence only if he has fallen short of the standard of reasonable care. This present application of the rule may give some reassurance to surgeons and anaesthetists.

A DANGEROUS WORD

Much trouble is caused to the courts and much disappointment to surviving relatives by testators who make their own wills without legal advice. One common pitfall is the use of the word "children," which bars illegitimate children unless they are fully named. The word "money" is even more dangerous. Countless testators must have used it on half-sheets of notepaper and stationers' will forms with lamentable results. A wealthy lady died recently leaving investments worth nearly £33,000, a bank account, some dividends, rents, and income-tax rebate due, household goods, and some valuable freehold property. She made a will on a form purchased from law stationers, without legal aid, and used the phrase: "I direct that all monies of which I die possessed of [*sic*] shall be shared by my nephews and nieces now living"—listing fourteen people, one of whom was a sister. The judge called upon to disentangle this will held that "monies" covered only the dividends received or accrued, the cash at the bank, the rents due and the tax rebate, not the investments, the freeholds, or the household goods.

His decision was taken to the Court of Appeal and the Master of the Rolls upheld it.[3] The court is bound by a rule which, although it was formulated in 1725,[4] is too firmly established for the court to alter. It lays down that the word "money" in a will must be construed in what is called its "strict" sense unless the context permits it to be given an extended meaning. The Master of the Rolls described the rule as a blot on our jurisprudence, and said that one of its anomalies is that the "strict sense" of "money" is a sense that has been invented by the courts themselves partly in order to mitigate the rigour of a rule confining "money" to actual cash. The special category known as "money in the strict sense" includes money in no strict sense, such as moneys on drawing account at the bank. The category, however, is closed, and the Master of the Rolls could not extend it in the absence of a context in the will permitting him to do so. He observed that since 1725 the habit of investment has spread so widely that millions of persons now possess securities which they commonly refer to as their "money." It would, he thought, be a grave national misfortune if such persons were to make home-made wills referring to their "money" and thus die intestate so far as their savings were concerned. Nevertheless, the court had overlooked in 1923 and 1929 two opportunities of restating the rule, and he did not think that it would now be justified in saying that the rule no longer bound it. The other Lords Justices shared his regret at being bound by this authority. Parliament has made every effort to induce citizens to invest all their spare income in various forms of Government loans, and the thorough patriot may not be able to afford legal assistance in making a will. Many poor testators cannot afford it in peacetime. The legislature ought in fairness to pass an Act amending the present obsolete construction of "money" in a will.

---

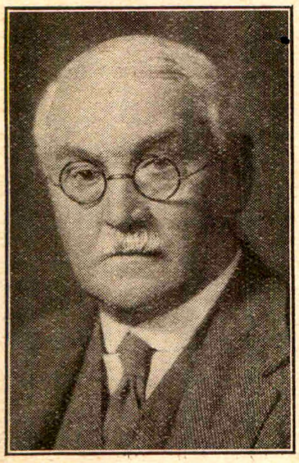
Obituary

EDWARD FAWCETT, M.D., F.R.S.

Prof. Edward Fawcett, F.R.S., the eminent anatomist, died suddenly while walking in Park Street, Bristol, on September 23. For over 40 years he was an outstanding figure in the Bristol Medical School, to which he brought the great anatomical tradition from Edinburgh.



Born on May 18, 1867, the son of Thomas Fawcett, B.A., he was educated at Blencow Grammar School, Cumberland, and studied medicine at the University of Edinburgh, graduating M.B., C.M. in 1889 and M.D. (with gold medal for his thesis) in 1906. He was a demonstrator of anatomy at the Edinburgh School of Medicine during his two final years, and then taught for three years in the dissecting room at the Yorkshire College, Leeds, until 1893, when he was appointed to the chair of anatomy at University College, Bristol. After the creation of the University of Bristol in 1909 he continued his work as professor of anatomy and dean of the Faculty of Medicine, and held both offices until his retirement in 1934, when he was made Emeritus Professor. He represented Bristol University on the General Medical Council for ten years, and was Long Fox Lecturer at Bristol in 1910. He gave the Arris and Gale Lecture before the Royal College of Surgeons of England in 1912.

Prof. Fawcett was president of the Anatomical Society of Great Britain and Ireland in 1927-9 and its treasurer for eleven years. At the International Medical Congress of 1909 in Budapest he was honorary president of the Anatomical Section. His services as examiner in anatomy were much in demand; he had examined for the Natural Sciences Tripos at Cambridge, and for the medical degrees of the Universities of Oxford, Aberdeen, Durham, London, Leeds, Manchester, Liverpool, and Birmingham, Queen's University, Belfast, and the National University of Ireland. He was elected F.R.S. in 1923 in recognition of his contributions on anatomical and embryological subjects, more particularly concerning the development of the human skeleton and of the mammalian cranium. He wrote no book but published many papers in the *Journal of Anatomy*. Prof. Fawcett was deeply interested in ecclesiastical architecture and served as president of the Bristol and Gloucestershire Archaeological Society a few years ago. His son is Mr. Alan Wordsworth Fawcett, F.R.C.S., surgeon to the Sheffield Royal Infirmary.

ERNEST LLOYD JONES, M.D.

We regret to announce the death of Dr. Ernest Lloyd Jones, senior consulting physician, Addenbrooke's Hospital, Cambridge, which occurred on Sept. 16, in his 80th year. Dr. Lloyd Jones was born at Bowdon, Cheshire, and was educated at the Manchester Grammar School. Obtaining a Clothworkers' Scholarship he came up to Downing College, Cambridge, in 1882, taking the Natural Sciences Tripos in 1885. He won the Senior Science Scholarship at St. Bartholomew's Hospital in 1886, in due time becoming house-physician there, having qualified M.B., B.Ch. in 1888. He took his M.D. degree in 1891. In 1894 he won a research scholarship of the British Medical Association. Returning to Cambridge he became demonstrator of pathology under Prof. Roy, and also pathologist to Addenbrooke's Hospital. Although in active practice until some eighteen months of his death, Dr. Lloyd Jones retired from the honorary staff of Addenbrooke's as senior physician in 1927. For many years he had also been on the visiting staff of Papworth Village Settlement, being a member, and latterly chairman, of the committee of management. In the last war Dr. Lloyd Jones served as a major on the staff of the First Eastern General Hospital, and was also inspector of tetanus cases in the Eastern Command. He was president of the Cambs and Hunts Branch of the British Medical Association in 1925-6, and a past-president of the Cambridge Medical Society. In 1901 he married Constance Mary Brooke. They have one daughter. His medical works include *Chlorosis, the Special Anaemias of Young Women, its Causes, Pathology, and Treatment.*

A fellow of the Geological Society, and of the Cambridge Philosophical Society, Dr. Lloyd Jones was writing at the time of his death a book on foraminifera, on which subject he was an acknowledged authority. As a young man he explored the Hoyle's Mouth and Coygan Caves in South Wales, and had presented several fossil specimens to the museums of geology and archaeology at Cambridge. He had a wide range of interests, with an intimate knowledge of many aspects of Nature collected on rambles on seashore and countryside. The cries and habits of birds were always an absorbing interest of his, and his delight in caring for individual animals and plants was an inspiration in itself. He had a real concern for his patients and put his professional service above all thoughts of remuneration, and frequently, and especially during the last few years of failing strength, without any consideration for his own health. Many a one has been braced and comforted by his cheery stories. He had a most kindly and gentle nature, and his patients, both in private and hospital practice, looked upon him as a real friend. It can truly be said of him that he was a beloved physician. H. B. R.

JAMES R. KERR, Ch.M.

The death of Dr. J. R. Kerr, C.B.E., of Southport on Sept. 21 marks the end of a distinguished and honourable career. Ten years after taking his degree in the University of Glasgow and holding resident appointments in the Western Infirmary and the Royal Hospital for Sick Children he went to France, and under the French Red Cross he became surgeon-in-chief to the Hôpital de l'Alliance at Yvetot. This was the opportunity for which he had been preparing, and his work earned him a fine reputation. From this service he came home to take charge of the special orthopaedic hospital maintained by Messrs. Pilkington Brothers at St. Helens. Here Kerr applied himself to the study and practice of rehabilitation. He was in the van in this country in this work. His contribution to it has perhaps hardly been recognized, but the hospital at St. Helens achieved a reputation under his charge, and was visited by many interested in rehabilitation after industrial accidents as well as after war injuries. When the British Medical Association met at Glasgow in 1922 he was secretary of the Section of Industrial Diseases and Forensic Medicine. He served as chairman of the St. Helens Division in 1922-3 and at the time of his death was chairman of the Southport Division. In practice in Southport, Kerr joined the staff of the infirmary as surgeon, and at the beginning of the present war was appointed also to the staff of the Emergency Hospital, where he had charge of beds. His colleagues and many friends will miss his robust company and his loyal friendship. K. W. M.

The special hospital at St. Helens, to which Kerr returned after his strenuous two years at Yvetot during the last war, was a true rehabilitation centre, where injured workmen and military casualties were treated from the time of their injury until their return to work. The results obtained in this way were so good that the hospital was continued for several years after the war. It was one of the first hospitals directly connected with industry in which active surgical work and rehabilitation were carried on to their logical termination, and the influence of Kerr was seen in every detail of the hospital's work. He transferred to Southport almost 20 years ago, and as a member of the surgical staff of the Southport Infirmary devoted himself with the same whole-heartedness, to the great benefit of the staff and of the people of the district. He always continued his interest in the work which he initiated at St. Helens, and during the present war he had been very active in carrying out a similar line of treatment in the very large

Southport E.M.S. Hospital. He will be remembered by all who knew him for his extreme kindness, his capability, the assiduity with which he carried out his work, and the many contributions which he made to the literature of the surgery of industrial injuries. In the present war he had suffered the loss of one of his three sons, a second son is a prisoner of war, and a third is now an active member of the surgical team of one of the large hospitals in the Middle East. To them and to his widow will be extended the sympathy of all who knew him. T. P. McM.

PROF. DAVID WATERSTON

Prof. D. R. Dow, M.D., University College, Dundee, sends the following appreciation:

The death of Prof. David Waterston removed one of the distinguished anatomists of the Edinburgh School, and a familiar figure for the past 28 years in the life of the University of St. Andrews. As successor to Musgrove he became the second occupant of the Bute chair of anatomy, and his tenure of office has been a memorable one. At the time of his appointment in 1914 the number of entrants to the Faculty of Medicine in our University was comparatively small, but he forecast that there would be a substantial increase, that our medical school would play a more important part in medical education, and his ability and influence have undoubtedly contributed to this. Under his direction the department of anatomy has undergone progressive development. He felt that the work should be carried out in an environment as pleasing as possible, and free from the horrors which haunt the mind of the beginner, and thus to-day there stands in St. Andrews a monument to his aim—a dissecting room of modern design and picturesque appearance.

Waterston was a man of wide interests, but he was first and foremost an anatomist, extending his study not only to the human but to the comparative, and science has benefited from his industry in these fields. His own career, as one would expect, was influenced by Sir William Turner. One could not fail to be impressed by his precision in expression, his critical attitude to any scientific statement, and his powers of observation always keen and astute, his eager mind stretching out after more and more facts. His numerous researches include papers on general anatomy, anthropology, and embryology. He possessed a fine collection of microscopical sections of early human embryos which enabled him to model in wax many specimens which, after careful and painstaking examination, have lightened the field of human embryology. Mounted in album form, photographs of these serial sections have found a place in many laboratories of this country. Much of his technical skill was directed to making the science of anatomy a living one, and we have testimony to this in his volume *Anatomy in the Living Model*. I spent much time with him when he prepared the orthogonal projections of the head and neck and abdomen which formed a large part of this publication, and it is almost unnecessary for me to testify to the care and precision with which this work was done. He was also one of the contributors to Cunningham's *Textbook of Anatomy*, in which he presented a lucid and up-to-date description of the digestive system. As joint editor of the *Edinburgh Stereoscopic Atlas of Anatomy*, the vision of many students has been enlightened as they reviewed in rapid succession photographs of his own handiwork.

In addition to such specialized study he retained a keen interest in clinical medicine, and found scope for his ingenious mind in the problems which presented themselves in the work of the James Mackenzie Institute. He looked forward with enthusiasm to the arrival in St. Andrews of Sir James Mackenzie, and for many years each enjoyed the privilege of work and friendship with the other. After his death the Institute found in Waterston a staunch and able leader, while as one of its research workers he conducted experiments on himself in order to elucidate the mechanism of pain—a contribution of the highest value. Generations of students of the Universities of Edinburgh, London, and St. Andrews will remember with appreciation how the teaching of anatomy was enhanced by the freshly dissected specimens which accompanied each demonstration and by the blackboard, on which Prof. Waterston had ample scope for his artistic talent. The entrant medical will reflect on the warmth of the reception and introduction to University life given by the Adviser of Studies. Outside the sphere of work as a Regent he was kind, hospitable, and interested. To those who were associated with him in his work, his distinctive personality and influence were a source of continual interest, encouragement, and stimulus. To junior members of his staff he was invariably courteous, and never too busy to listen to their problems or to help them by advice.

Dr. **WILLIAM BRUCE WISHART**, for many years a well-known Halifax practitioner, died on September 4 in Edinburgh. He graduated M.B., Ch.B.Ed. in 1904 and went to Halifax five years later, after holding house appointments at the North Staffs Infirmary and Stoke-on-Trent Eye Hospital. His connexion with the Halifax Royal Infirmary began as house-surgeon, and he was later appointed honorary surgeon, retiring from the active staff in 1938. During the last war he served with the R.A.M.C. in France and Belgium. Dr. Wishart joined the B.M.A. in 1907 and was chairman of the Halifax Division in 1926–7.

The announcement of the death of Mr. **ALWYNE T. COMPTON**, F.R.C.S., will be received with profound regret by his many friends and colleagues at the German Hospital, Dalston, and by his former pupils at King's College, University of London. Born in 1874, he received his medical education at St. Bartholomew's, qualified in 1901, and obtained the F.R.C.S. in the following year. On the outbreak of the present war, although he had retired from practice, he generously offered his services once more at the hospital at Dalston where he had acted with distinction for many years. The return to active work was unfortunately attended by the occurrence of a stroke which left him for the remainder of his life with a partial paralysis. Recently his house in Devonshire was bombed by enemy action, and owing to a fall afterwards his hip was fractured. He died on Sept. 9 in his old hospital, where he will long be remembered as an honoured and faithful servant in the cause of his profession. In addition to his surgical work, Compton's anatomical and pathological knowledge was very extensive. His case notes mostly contained illuminating drawings. His anatomical teaching at King's College was held in high esteem. From his father, who was a well-known landscape-painter, he doubtless derived his skill as a draughtsman.

Mr. R. W. Crawford Treasure, whose death was reported in the *Journal* of Sept. 12 (p. 326), saw service in France in the last war, only going to India in 1916 after being invalided from the Army.

Universities and Colleges

UNIVERSITY OF GLASGOW

The Dean of the Faculty of Medicine gives notice that, at the desire of the Secretary of State for Scotland, the University of Glasgow has decided not to accept, for the duration of the war, students wishing to enter upon the course for the Diploma in Public Health.

The Services

The D.S.C. has been awarded to Temp. Surg. Lieuts. H. S. A. Corfield, K. C. Jeffery, and R. D. Robinson, R.N.V.R.

CASUALTIES IN THE MEDICAL SERVICES

Lieut. **HEDLEY DOUGLAS VENNING**, R.A.M.C., was killed in action in the Middle East in Sept. He was born on March 2, 1916, and studied at Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1939, and graduating M.B., B.S.Lond. in 1940. He had held house posts at Torbay Hospital, Torquay, and, later, an assistantship in Chester. He entered the R.A.M.C. as a temp. lieut. in Aug., 1941. He leaves a widow.

Prisoners of War.—Lieut. D. Christison, R.A.M.C., Capt. D. Foskett, R.A.M.C., Major D. A. Macpherson, R.A.M.C., Capt. R. G. Main, R.A.M.C., Capt. C. L. Malhotra, I.M.S.

Missing.—Surg. Lieut. H. E. D. Gale, R.N.V.R., Capt. J. S. McConnachie, R.A.M.C., Lieut. W. H. McDonald, R.A.M.C., Lieut. K. W. Todd, R.A.M.C.

DEATHS IN THE SERVICES

Lieut.-Col. **WILFRID EDWARD BRIERLEY**, I.M.S. (ret.), died at Kitamaiyu, Ruiru, Kenya Colony, on Sept. 11, aged 61. He was born on Jan. 17, 1881, and was educated at the University of Manchester, graduating M.B., Ch.B.Vict. in 1904. He also studied at King's College and the London Hospital, taking the M.R.C.S., L.R.C.P. in 1905, and the F.R.C.S. two years later. He entered the I.M.S. as lieut. in 1908, became lieut.-col. after twenty years' service, and retired in 1933.

No. 36

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 12.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* rises occurred during the week in the incidence of scarlet fever 146 cases, diphtheria 68, dysentery 34, and typhoid 23, and decreases for measles 380, whooping-cough 123, puerperal infections 73, and acute pneumonia 60.

Within the counties the notifications of diphtheria, acute pneumonia, and whooping-cough showed only slight variations from last week's totals, the only marked change being in Staffordshire, where 26 fewer cases of whooping-cough were reported.

Scarlet fever notifications rose because of an increase of 57 cases in Yorks West Riding, of 40 in Lancashire, and of 27 in Essex; in London the notifications dropped by 33. In Yorks West Riding the recent outbreak has been particularly severe in Goole M.B., where hospital accommodation has been strained and patients have had to be sent to neighbouring hospitals.

The incidence of measles declined for the tenth consecutive week. In Leicester, however, there was an increase of 53 cases due to an outbreak in Coalville U.D. 57 cases. The Durham notifications also rose by 41, due to an outbreak in Crook and Willington U.D. 55 cases. The largest decreases were recorded in Yorks West Riding 130, Essex 74, London 74.

An outbreak of typhoid in Bedfordshire, Biggleswade R.D., involved 18 persons and resulted in the largest weekly total recorded for this disease since last October.

No new outbreak of dysentery occurred during the week. The rise in notifications was due to an increase in those outbreaks which began last week. The chief centres of infection were: Oxfordshire 41 (Bullingdon R.D. 5, Oxford C.B. 8), Lancashire 21 (Warrington R.D. 14, Manchester C.B. 6); Norfolk 16 (Norwich C.B. 12); London 13 (Woolwich 7); Surrey 12 (Epsom and Ewell M.B. 7).

In *Scotland* the incidence of infectious diseases showed little change from last week, although acute primary pneumonia and scarlet fever rose by 18 and 43 cases. A small rise in scarlet fever was fairly general throughout the country, but the excess of pneumonia was mainly confined to Glasgow.

In *Eire* there was a rise in the incidence of poliomyelitis. During the past two weeks 25 cases have been notified, 10 of which were reported from Dublin.

Small-pox

A report has been issued by the Medical Officer of Health for Glasgow on the recent outbreak of small-pox. Altogether 36 persons contracted the disease and 8 died: 11 of the cases were due to direct infection on the ship, and 25 cases occurred in the general population.

No satisfactory explanation can be given for the spread of the infection among the civilians in different districts of the city. The report emphasizes the success of vaccination in preventing a major epidemic and makes strong recommendations concerning the vaccination of crews and passengers travelling from the East.

Quarterly Returns

England and Wales.—The returns for the June quarter show that, despite three years of war, an improvement was effected on the general peacetime trend of the vital statistics. The birth rate was 16.2 per 1,000, which, with the exception of 1940, when the rate was the same, was the highest birth rate in any second quarter since 1932, when it was 16.5. The infant mortality was 47 per 1,000 live births, 7 below the average of the ten preceding second quarters. The stillbirths were 3.3% of the total births registered. The general death rate was 11.3 per 1,000—the lowest rate for this quarter since 1933—compared with a rate of 13.6 in 1941. The natural increase—excess of births over deaths—was 50,723, compared with 43,777, 46,980, and 7,228 for the corresponding quarters of 1939-41.

Northern Ireland.—A favourable experience was enjoyed by Northern Ireland during the second quarter of the year.

The births corresponded to a rate of 24.7 per 1,000, compared with 21.7 for the average of the second quarters of the five preceding years. The infant mortality was 71 per 1,000 births, or 1 below the five-year average. The general death rate was 13.2 per 1,000; this rate was 4.7 below that for the corresponding quarter of 1941 and 1.4 below the average rate for the second quarters of the five preceding years. The death rate from tuberculosis was 1.01 per 1,000, which, although 0.11 below the rate for the June quarter of 1941, was 0.03 above the five-year average.

Returns for the Week Ending September 19

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,882, whooping-cough 1,150, diphtheria 878, measles 2,998, acute pneumonia 401, cerebrospinal fever 72, acute poliomyelitis 29, dysentery 184, paratyphoid 8, typhoid 13.

Medical News

At a meeting of the Royal Sanitary Institute to be held at Hallam Municipal Hospital, West Bromwich, on Saturday, Oct. 10, at 11 a.m., Dr. W. S. Walton will read a paper on "Some Practical Health Problems of To-day from the Medical Officer of Health's Standpoint."

A memorandum issued by the Greek Government states that according to the Red Cross about 40,000 persons, including a high proportion of children, in Athens and the Piraeus died of famine and diseases caused by malnutrition between Oct. 1, 1941, and Jan. 26, 1942. The quality of such food as is available is low through lack of fats. Each daily ration contained only 500 calories against the 2,500 issued by feeding centres in the previous winter. The situation in other cities such as Salonika, Patras, and Volo, as well as in the islands of Chios and Syra, is equally tragic.

Sulphanilamide powder (4 oz.) and powder dredgers are to be issued to first-aid points for use where there is difficulty in removing a casualty to a first-aid post or hospital. Ministry of Health Circular No. 2664 states that a thin, uniform coating of the powder should be shaken on the surface of the wound and a dressing applied. Hydrogen peroxide is to be issued to first-aid posts and gas-cleansing stations for the treatment of lewisite burns.

Doctors wishing to engage dispensers who are subject to the Employment of Women (Control of Engagement) Orders must notify the Central Pharmaceutical War Committee, 17, Bloomsbury Square, W.C.1, which is the approved agency for the Ministry of Labour under the Orders, giving full particulars of the vacancy to be filled.

The 114th annual meeting of the Medical Charitable Society for the West Riding of the County of York was held at Leeds under the presidency of Dr. T. Wardrop Griffith. The society was founded in 1828, and since that time it has distributed £111,155 among the applicants for help. For the ensuing year, forty-two grants, totalling £1,868, were made. It was reported that a form of covenant had been circulated to the members, who were urged to enter into it. The result of this would be that the society could recover income tax on such subscriptions. It was decided that a part of the extra income resulting from this would be distributed as a Christmas gift to each recipient of a grant.

Dr. Austin William Byrne, expert in public health, Egyptian Government, has been appointed a C.B.E. (Civil Division). The citation in the *London Gazette* states that since the beginning of the war Dr. Byrne has co-operated with the medical services of the British Army in Egypt and has been particularly helpful in co-ordinating the services of the Egyptian Government hospitals in connexion with facilities for the treatment of prisoners of war, which, without his help, would have been an insurmountable problem.

Mr. Robert Brough, registrar of the Glasgow University General Council and acting secretary of the University Court, has retired after nearly 40 years' service to the University. The General Council is organizing a testimonial to him, and subscriptions (limited to 5s.) should be sent to the Clerk, Mr. David M. Hutchison, M.A., LL B., 82, West Regent Street, Glasgow, C.2.

The September quarterly number of *Medicine Today and To-morrow* is mainly devoted to "The Socialist Programme for Health," which takes the form of a statement of policy in the light of the Medical Planning Commission's interim report. Copies may be had (price 6d.) from 176, Kew Road, Richmond, Surrey.

We have received from Dr. J Tyler Fox (treasurer of the British Branch of the International League against Epilepsy (The Homestead, Lingfield, Surrey) a copy of the last issue of the periodical *Epilepsia*, dated July, 1941, and printed in America by the Graphic Press, Newton, Massachusetts. Present conditions in Europe make it impossible to edit and publish the journal in Denmark.

At the first meeting recently of the Colonial Research Committee Lord Cranborne said that the two functions of the committee were to advise on schemes for assistance from the £500,000 a year provided under the Colonial Development and Welfare Act for "research and inquiry," and to survey "the whole range of research in Colonial studies." Among the members of the committee are Prof. A. V. Hill, Sir Edward Mellanby, and Dr. W. W. C. Topley.

Mr. Bowdler Henry has been appointed honorary consulting oral surgeon and consultant adviser to the Royal Netherlands Army, the Fighting French Forces, the medical section of the Czechoslovak Red Cross, the Central Committee, Polish Red Cross, and the Royal Norwegian Ministry of Social Welfare.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and *B.M J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

QUERIES AND ANSWERS

Aspirin for Asthma

Dr. K. TEMPLE BROWN writes: A. K. describes dramatic success with homoeopathic doses of aspirin in asthma. I feel it only right to record the experience of a colleague of mine, equally dramatic. He has suffered from bronchial asthma for years and used to tolerate aspirin, but a few years ago took 15 grains for a cold and within a quarter of an hour was in the grip of the worst bronchial spasm he had ever known, requiring morphine and oxygen inhalations. He tells me that his is not an isolated case and that phenacetin produces the same effect. Other readers of the *Journal* may be glad of this warning. I know of no pharmacological explanation of A. K.'s findings—but faith moveth mountains. Certainly, I know of asthmatics unrelieved by ephedrine but relieved by "special ephedrine," which consisted of calc. carbonate. Apart from that, it seems likely that in his patient aspirin's sedative action depresses a psychogenic factor in the aetiology of her bronchial spasm.

Dr. M. W. BROWDY (London, W.) writes in reply to A K. (Sept. 19, p. 356): Asthma is often of psychological origin: a somatic symptom in a neurotic syndrome. Hence aspirin may give relief in two ways: by suggestion and mild sedation.

Dr. J. E. O'LOGHLEN writes in reply to A. K.: The effect of aspirin in asthma is due to a lowering of surface blood tension. Incidentally 20% of asthmatics are very sensitive to aspirin; 50% of all asthmatics respond favourably to any indifferent treatment.

Desert Sores

Col. C. RICHARDSON-WHITE (Merthyr Vale, Glam.) writes: Is the desert sore our old friend the veldt sore which we treated in the Boer War and the septic sore of 1914-18 in Egypt, Sinai, and Palestine? I commanded a C.C.S. throughout the last war, nearly all the time in the East. During the advance on Gaza and afterwards hundreds had septic sores and filled the hospitals, thus depleting the front line. At a field laboratory at Gaza one of the officers discovered that the film on these sores had a diphtheritic appearance. He tried for Klebs-Loeffler bacillus and found it, together with the *Streptococcus pyogenes*. Orders were issued to all medical units to apply for antidiphtheritic serum, and to inject 3,000 units in all cases of septic sores. The result was like a miracle. All the cases responded and were soon cured.

Income Tax

Appointment

W. is assessed under Schedule E in respect of a salary of £306 from an appointment as works M.O. Can he claim to have the salary included in his Schedule D assessment?

⁂ There is no legal claim, but it is a common and well-established practice of the Inland Revenue Department to adopt that procedure if requested to do so by the taxpayer. We suggest that W. apply accordingly to the local inspector of taxes.

Married Woman

B. is married and has one child under 16 years of age and a dependent widowed mother. Her husband is interned and has at present no income of his own. She has been assessed as assistant M.O.H. as a single person (with £80 personal allowance only) and no deduction has been made for professional subscriptions or domestic help.

⁂ On the basis that B. is "living with" her husband in intention, although temporarily apart for reasons beyond their control, the husband should strictly be assessed in respect of B.'s earnings. But whether he or she be assessed, the allowances due are

£140 (for married persons) and £80 "wife's earned income allowance," as well as £50 for the child and £25 for the dependent relative. A declaration of income and claim to these allowances is, however, necessary by the husband We suggest that B. explain the circumstances to the local inspector of taxes and ask him for a copy of the appropriate form of claim No allowance is due for domestic expenses; professional subscriptions are allowable only if membership of the association in question is a condition of the appointment.

Commencement of Liability from Employment

M. G. qualified in July, 1940. He earned, £200 between that date and April, 1941, and another £200 in the year to April, 1942, including one month's earnings from his present employment (at £600 per annum) in March, 1942. How should his liability be calculated?

⁂ On the above facts the appointment is a new source of income, and he is liable on the basis of the earnings of the current year for the part of 1941-2 and the whole of 1942-3. The deductions made for tax for the year commencing November, 1942, will be in respect of the income for the year commencing April, 1942. If the appointment should terminate, M. G. should at once inform the inspector of taxes, but it is unlikely to do so at such a time as will leave him in the position of having paid more tax than was due on his earnings.

Assistant's Board and Lodging

T. C. is "employed as an assistant at a salary of £500 per annum, all found; by this the agreement means that my employer pays £2 12s. 6d. per week board and lodging for me" Is he assessable, or is his employer assessable on this sum?

⁂ His employer is clearly entitled to treat the payment of the weekly amount as deductible for income tax purposes. As regards T. C., *prima facie* he is *not* liable, as benefits are not taxable unless they are received in money or in a form convertible into money. The only contention which could be raised in favour of his liability is that if he has contracted with his landlady to pay her £2 12s. 6d. a week and his principal pays it for him, then the principal is in law and substance paying him money by discharging his debt It may be desirable therefore to see that the contract for the board and lodging is between the employer and the landlady and not between T. C and the landlady.

LETTERS, NOTES, ETC.

Fuel Economy

Prof. R. J. Willan writes: During the present emergency could not an appeal be made to all surgeons to refrain from the present wasteful practice of using running hot water when making their hands surgically clean. An equal result can be obtained by using two or three changes of hot water. Running hot water is a luxury but is *not* a necessity. A surgical team of, say, four persons, scrubbing up their hands for an operation for the requisite ten minutes, can consume and waste an unjustifiable amount of fuel.

Bleeding from Tooth Sockets

C R.-W. writes: With regard to bleeding from tooth sockets, what is wrong with the old-fashioned friars' balsam (tinct. benz. co.)? It is a bit messy, I suppose, but always efficient. A plug of cotton-wool soaked in this quickly does the trick. I have never found it to fail.

External Styptics

Dr. C. Charnock Smith (Hastings) writes: May I suggest as useful styptics, which can be easily carried in one's bag for use in the case of bleeding tooth sockets, epistaxis, and haemorrhage from a fungating malignant growth, the following to be used locally: adrenaline chloride 1 in 1,000; "stypven"; turpentine; stick of nitrate of silver; and liq. ferri perchlor fort. or gossypium ferri perchlor. *B P.C.* used dry.

Treatment of Scabies

Dr. J. E. O'Loghlen (London, W.1) writes: For the past 20 years I have always treated scabies with the application of sodium hyposulphite and hydrochloric acid. It is most effective, being cheap, clean, and convenient. I think it was first introduced in France by Leblanc-Dutheil (Nantes). Some 12 years later it was used by Demjanovic at the State Dermatological Institute, Moscow, and later in Germany at the Skin Clinic, Düsseldorf. The technique is as follows. Two solutions are used: (1) sodium hyposulphite 200 parts to 1,000 water; (2) a 5% solution of hydrochloric acid. The whole body is rubbed with solution No. 1, which is applied with a piece of cotton-wool and allowed to dry for a few minutes When dry, solution No. 2 is applied in the same way. The patient is then instructed to put on a shirt without drying the body and goes to bed. Next morning solution No. 1 is applied as before. This treatment is carried out for 2 successive days; very rarely is it necessary to continue treatment on the third day. Having finished the treatment the patient puts on clean underwear and returns to work. There is no necessity for any applications of ointments or soap. The underclothing is not damaged, the skin is not irritated, the solution has no odour, and the itching stops at once. This treatment has been carried out in many thousands of cases, and is particularly suitable in the treatment of large numbers—schools, military barracks, etc. Solution No. 1 is sometimes used more concentrated—1 to 3—but the strength of solution No. 2 is always 5%.

Army Discharge

"Devonian" writes: From a rural community of approximately 2,000 over 60 men have entered various Services since the outbreak of war, all being medically examined by the same medical board. To date 11 have been returned to civilian life "unfit for any form of military service." All had been graded A1. I have seen their "papers." One, having no previous medical history of note, discharged with bronchiectasis, now has an arduous day as a milk roundsman. Another, an agricultural labourer, was discharged with duodenal ulcer; he has not sought advice or assistance for his complaint during the 12 months he has been at home. A general carpenter sent back with "rheumatism" has not missed a day's work since his return, and spends most of his time outdoors on the roofs of Government buildings! Discharged "because he could not wear Army boots," a general labourer walks at least 4 miles a day and earns not less than £5 per week An Army driver was sent home "because he had attacks of giddiness when driving trucks"; he now handles charabancs and 8-wheeler cattle trucks. Similar cases could be detailed. Apparently no re-examination is possible. One only of the 11 has required medical attention, and that for an unrelated complaint After a week or so at home it would appear that the disability vanishes and the prospect of a lucrative job works magic as a permanent therapeutic power The men concerned all "wanted to get out," and one or two have admitted that they "kept at it until they were given their ticket." Is this how we win the war?

MEDICINE 100 YEARS AGO

Extracts from an article entitled "Sketches of American Physicians" by Nathaniel Chapman, M D., reprinted in the *Provincial Medical Journal* of October 1, 1842, from the *Medical Examiner*:

"Dr. Chapman was born in Fairfax county, Virginia, on the 28th of May, 1780, and has, therefore, nearly completed his sixty-second year. His paternal ancestor came to Virginia with the first colony, was a captain of cavalry in the British army, and, according to an authentic tradition in the family, was the youngest son of a cousin german of Sir Walter Raleigh. The family settled on the river Pomonkey, some twenty miles from Richmond; but the branch from which the doctor is descended migrated about a century and a half ago to Maryland, and fixed itself on an estate on the banks of the Potomac, nearly opposite Mount Vernon, which is still in their possession. The doctor's father, however, went to Virginia, upon his marriage, where he afterwards remained. Dr. Chapman received his early education at the Classical Academy of Alexandria, D.C., founded by General Washington, where he was six years. He subsequently spent a short time in two colleges, though not long enough to owe either any obligation. He came to Philadelphia in the autumn of 1797, to commence the study of medicine with the late Professor Rush, of whom he became a favourite pupil. . . .

"In 1801 he went abroad, and spent four years, chiefly at Edinburgh and London. He remained a year in London, the private pupil of Abernethy, and thence passed to Edinburgh. Edinburgh was then celebrated equally for her school of medicine and her literary and scientific society. Students of medicine resorted thither, as now to Paris, from all parts of the world. Nearly all our American physicians of the olden time—Morgan, Shippen, Kuhn, Rush, Wistar, and many others—received their education at Edinburgh. It may be supposed that Dr. Chapman made the most of his opportunities in the distinguished circle of the modern Athens. . . . Dr. Chapman returned to this country in 1804. . . . He was the physician and confidential friend of the Count de Survilliers (Joseph Bonaparte), during his long residence in Philadelphia and its vicinity. From the Count he gathered a large fund of interesting anecdote of the illustrious brother of the ex-king, and the men and scenes of his eventful times, from which the doctor occasionally draws . . . As a practitioner, Dr. Chapman is distinguished as much for the charm of his manner in the sick chamber as for skill and success in prescribing. His lively conversation and ever-ready joke are often more effective than anodyne or cordial Indeed, in cases of trifling importance, the doctor sometimes prescribes little else. In pleasant chit-chat, both patient and physician forget the object of the visit, and the doctor will depart and 'leave no sign' for pill or bolus"

⁂ The *Provincial Medical Journal* subsequently became the *British Medical Journal*.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 10 1942

TUBERCULOSIS IN LONDON IN WARTIME

BY

W. ALLEN DALEY, M.D., F.R.C.P.
Medical Officer of Health, L.C.C.

AND

B. BENJAMIN, B.Sc., F.I.A., F.S.S.
Statistical Branch, L.C.C. Public Health Department

In order to assess the effect of war conditions upon the incidence of tuberculosis in London, a review of the notification records was undertaken. The results of such an analysis in respect of an urban area in which conditions immediately before the outbreak of hostilities were stable have helped to throw some light on the problem of controlling tuberculosis, and are recorded here in the hope that they will be of use to other workers in this field.

Pulmonary Tuberculosis

The general trend of pulmonary tuberculosis in London is indicated by Table I, which shows the numbers of formal primary notifications and the numbers of deaths since 1913, together with the corresponding rates.

TABLE I.—*Primary Notifications (a) of and Deaths from Pulmonary Tuberculosis in the Administrative County of London*

Year	Formal Primary Notifications		Deaths	
	No	Annual Rate per 1,000 Living	No	Annual Rate per 1,000 Living
1913	(b) 19,218	4·25	5,863	1·30
1914	(b) 16,467	3·64	6,331	1·40
1915	(b) 14,712	3·26	6,715	1·49
1916	(b) 13,547	3·01	6,364	1·41
1917	(b) 14,870	3·31	6,768	1·51
1918	(b) 15,670	3·50	6,920	1·55
1919	(b) 12,356	2·76	5,197	1·16
1920	9,202	2·06	4,675	1·04
1921–5	38,807	1·71	22,980	1·01
1926–30	34,353	1·53	20,247	0·90
1931–5	29,569	1·38	17,075	0·79
1936	5,176	1·25	2,849	0·69
1937	5,455	1·33	2,888	0·71
1938	5,200	1·28	2,590	0·64
1939	4,691	1·24	2,650 (d)	0·70
1940	4,326	1·32 (c)	2,687 (d)	0·87
1941	4,577	1·78 (c)	2,552 (d)	1·10

(a) Excluding posthumous cases. (b) Not checked for duplicates (c) Based on the civilian population only—i.e., civil notifications per 1,000 civilians (d) Excluding non-civilians from Sept. 3, 1939

It will be seen that the decline in incidence, which had been continuous since the war of 1914–18, was arrested at the beginning of the present war. Although it is not clearly shown by the table, the increase in mortality actually preceded the increase in the rate of occurrence of new cases. The rise in the notification rate was not appreciable until the latter part of 1940; the notification rate for the first half of 1940 was not substantially above the level of the same period in 1938. The impact of war was reflected first in the earlier deaths of those in whom tuberculosis had already developed. It was not until later that the strain of war began to produce a rise in newly diagnosed infections.

The analysis of new cases which was made for the years 1938–41 embraced not only formal primary notifications but also posthumous notifications. The distribution of these new cases by age and the estimated rates per 1,000 living are shown in Table II.

TABLE II.—*New Cases of Pulmonary Tuberculosis in London (A.C.), 1938-41*

Age Group	1938		1939		1940 (a)		1941 (a)		Increase in Rate for 1941 compared with 1938 %
	No.	Rate per 1,000	No.	Rate per 1,000	No.	Rate per 1,000	No	Rate per 1,000	
0–4	105	0·42	76	0·40	60	0·53	104	1·64	290
5–14	228	0·42	161	0·39	103	0·55	198	1·74	314
15–24	1,484	1·52	1,353	1·43	1,130	1·42	1,150	1·89	24
25–64	3,262		2,917		2,592		2,631		
65+	224		236		202		250		
Not stated	2		24		18		24		
Total	5,305	1·31	4,767	1·26	4,105	1·33	4,357	1·87	43

(a) Excluding non-civilians.

It should be stressed that the validity of the rates shown in Table II depends upon the accuracy of population estimates on which they are based, the details of which cannot be adequately set out here owing to restrictions on space, but there is no doubt that the increase in the incidence of respiratory tuberculosis between 1938 and 1941, especially among children, is greater than that which could be attributed to errors in these estimates. Possible changes in the character of the population are dealt with in the discussion at the end of this article.

For comparative purposes the age distribution of deaths during the same period is shown in Table III.

TABLE III.—*Deaths from Pulmonary Tuberculosis in London (A.C.), 1938-41 (see note d, Table I)*

Age Group	1938		1939		1940		1941		Increase in Rate for 1941 compared with 1938 %
	No.	Rate per 1,000	No.	Rate per 1,000	No.	Rate per 1,000	No.	Rate per 1,000	
0–4	30	0·12	15	0·08	22	0·19	41	0·65	442
5–14	25	0·05	16	0·04	24	0·13	25	0·22	340
15–24	459	0·77	447	0·83	454	0·95	432	1·16	51
25–64	1,863		1,922		1,965		1,827		
65+	213		250		222		227		
Total	2,590	0·64	2,650	0·70	2,687	0·87	2,552	1·10	72

The sex distribution of new cases of pulmonary tuberculosis, 1938–41, is shown in Table IV.

For the purpose of Table IV non-civilians have been included in order that the sex proportions in the total populations to which the new cases are related can be regarded as comparatively stable. If non-civilians were excluded account would have to be taken of the different effect on the male and female civil populations of the calling up of Service personnel. It should be borne in mind, however, that the very fact that recruitment during the period under review has affected males

TABLE IV.—*New Cases of Pulmonary Tuberculosis in London (A.C.), 1938-41 (including Non-Civilians)*

Year	0–14			15–24			25–64			65+			Age Group Total (a)		
	M	F	M/F	M	F	M/F	M	F	M/F	M	F	M/F	M	F	M/F
1938	173	160	1·08	661	823	0·80	2,133	1,129	1·89	152	72	2·11	3,121	2,184	1·43
1939	111	126	0·88	654	699	0·94	1,913	1,004	1·91	170	66	2·58	2,868	1,899	1·51
1940	70	93	0·75	573	669	0·86	1,835	898	2·04	152	50	3·04	2,638	1,720	1·53
1941	164	138	1·19	621	722	0·86	2,001	880	2·27	188	64	2·94	2,987	1,815	1·65

(a) Including cases in which the age is not known

more than females implies that the search for new cases has been more intense among males than among females; this tends to produce a fictitious increase in the male-to-female ratio of new cases of respiratory tuberculosis.

When these considerations are taken into account it does not appear possible to draw from Table IV any sound conclusions as to the effect of the war upon the relative incidence of pulmonary tuberculosis among men and women respectively in the important 15–24 age group. At older ages it does appear clear that males have been more affected than females (as in the case of non-pulmonary tuberculosis, see Table VIII). With regard to ages under 15, the irregularity in the sex ratios is not greater than that which has been experienced in past years and, which might be expected having regard to the small numbers involved.

In the absence of precise information as to the sex components of the population of London it is not possible to carry the sex incidence analysis any further.

Non-pulmonary Tuberculosis

With regard to non-pulmonary tuberculosis, the background is given by the following figures, which tell the same story as does Table I for pulmonary tuberculosis.

TABLE V.—*Primary Notifications (a) of and Deaths from Non-pulmonary Tuberculosis in the Administrative County of London*

Year	Formal Primary Notifications		Deaths	
	No.	Annual Rate per 1,000 Living	No.	Annual Rate per 1,000 Living
1913	(b) 6,436	1·42	1,611	0·36
1914	(b) 3,862	0·85	1,666	0·37
1915	(b) 3,949	0·88	1,841	0·41
1916	(b) 4,084	0·91	1,641	0·36
1917	(b) 3,864	0·86	1,715	0·38
1918	(b) 3,517	0·79	1,526	0·34
1919	(b) 3,231	0·72	1,127	0·25
1920	2,461	0·55	1,070	0·24
1921–5	10,881	0·48	4,383	0·19
1926–30	8,971	0·40	3,080	0·14
1931–5	6,322	0·29	2,354	0·11
1936	1,056	0·26	363	0·09
1937	1,014	0·25	351	0·09
1938	982	0·24	347	0·09
1939	805	0·21	302 (d)	0·08
1940	653	0·20 (c)	318 (d)	0·10
1941	675	0·27 (c)	343 (d)	0·15

(a) Excluding posthumous cases. (b) Not checked for duplicates. (c) Based on the civil population only—i e, civil notifications per 1,000 civilians. (d) Excluding non-civilians from Sept. 3, 1939.

The age distribution of the new cases which have occurred since the beginning of the war is shown in Table VI, from which it is clear that the comparatively small rise in the notification rate for the population as a whole conceals very large increases in the rates for the younger age groups. These increases are much in excess of any variations attributable to margins of error in the estimation of basic populations.

TABLE VI.—*New Cases of Non-pulmonary Tuberculosis in London (A.C.), 1938-41*

Age Group	1938		1939		1940 (a)		1941 (a)		Increase in Rate for 1941 compared with 1938 %
	No.	Rate per 1,000	No.	Rate per 1,000	No	Rate per 1,000	No	Rate per 1,000	
0–2	87	0·55	71	0·58	52	0·76	84	2·21	302
3–4	55	0·61	41	0·59	44	0·98	45	1·77	190
5–14	253	0·47	200	0·48	146	0·78	148	1·30	177
15–24	272	0·20	217	0·17	162	0·16	172	0·20	—

65+	40		26		24		40		
Not known	—		2		4		4		
Total	1,053	0·26	859	0·23	681	0·22	704	0·30	15

(a) Excluding non-civilians.

The death rates (per 1,000) from non-pulmonary tuberculosis in the same four years among children under 15 years of age were: 0.19, 0.17, 0.35, and 0.87 respectively—a progression which is in substantial agreement with the trend of new cases.

The distribution of new cases according to the site of the tuberculous lesion is shown in Table VII for both children and adults. The variations in the rates for the different sites are in the case of adults relatively small when normal yearly fluctuations are taken into account, except possibly in the case of meningitis. In respect of children, however, the changes in the rates are substantial. When all bones and joints are combined, the percentage increases in the rates for each site over the period 1938-41 are: all bones and joints, 184; abdomen, 141; peripheral glands, 215; meninges, 250; other sites, 269. Having regard to chance fluctuations, the difference between these percentages does not appear to be statistically significant, except in the case of tuberculosis of the abdomen, in which the increase seems to be significantly lower than for other sites.

As an indication that 1938 is a satisfactory base-year for the purpose of Table VII, the average site distribution of deaths from non-pulmonary tuberculosis during the immediate pre-war years is given below.

Percentage Distribution of Deaths from Non-pulmonary Tuberculosis in London (A.C.), 1931-8

Year	Bones and Joints	Intestines and Peritoneum	Central Nervous System	Other	Total
1931–8	15	10	41	34	100
1938	12	9	42	37	100

TABLE VII.—*New Cases (a) of Non-pulmonary Tuberculosis in London (A.C.), 1938-41: Distribution according to Site. Rates per 1,000 Living are shown in Parenthesis against the Numbers of Cases*

Age Group	Year	Site of Tuberculous Lesion

(a) Primary notifications, including posthumous cases. (b) Includes miliary and genito-urinary. (c) Excluding non-civilians.

TABLE VIII.—*New Cases of Non-pulmonary Tuberculosis in London (A.C.), 1938-41 (including Non-civilians)*

Year	0–14			15–24			25–64			65+			Age Group Total (a)		
	M	F	M/F	M	F	M/F	M	F	M/F	M	F	M/F	M	F	M/F
1938	223	172	1·30	144	128	1·13	154	192	0·80	12	28	0·43	533	520	1·03
1939	165	147	1·12	107	110	0·97	142	160	0·89	14	12	1·17	428	431	0·99
1940	117	125	0·94	80	94	0·85	142	120	1·18	10	14	0·71	353	353	1·00
1941	141	136	1·04	87	111	0·78	116	113	1·03	14	26	0·54	360	388	0·93

(a) Including cases in which the age is not known.

The sex distribution of new cases is shown in Table VIII, in which non-civilians have been included for reasons that have already been stated. The trend of the sex ratios indicates that at ages below 25, and particularly in the 15–24 age group, females have been more affected than males by the increased incidence. At the older ages it appears that males have been more affected than females.

Discussion

The experience of London, judged by the foregoing statistics, has been less favourable than in the country as a whole. Brief, and in some cases necessarily approximate, figures for England and Wales are given in Table IX.

TABLE IX.—*Tuberculosis Notification and Mortality Rates per 1,000 in England and Wales*

Year	Formal Notifications per 1,000		Deaths per 1,000 (b)	
	Pulmonary	Non-pulmonary	Pulmonary	Non-pulmonary
1938	0·92	0·31	0·53	0·10
1939	0·84	0·27	0·54	0·10
1940	0·87 (a)	0·25 (a)	0·59	0·11
1941	0·95 (a)	0·28 (a)	0·60	0·13
Increase 1938–41 (%)	3	−10	13	30

(a) Approximately, based on mid-1939 total population. (b) Excluding non-civilian deaths after Sept. 3, 1939.

Possible causes of this divergence are easier to suggest than to measure. Evacuation has probably had a selective effect upon the population. Some children who were ailing may have been kept back by their parents, and those who subsequent to evacuation showed signs of deterioration in health would probably have returned very soon. Among children actually attending school it has to be admitted that there is little evidence to support this suggestion in the clinical results of routine medical examinations carried out by school medical officers; the increased incidence of tuberculosis, particularly of the non-pulmonary form, was, however, greater in children of pre-school age, and many of the new cases among older children would not have attended school for some time prior to notification and would have missed routine examination. A probable effect of evacuation has been to increase the proportion of tuberculous persons in the population remaining. It would be expected that as they were ill they did not desire to leave home, and for the same reason (in many cases, also, their economic status would be low) it would be more difficult for them to find homes in reception areas. Inquiries made of representative boroughs reveal that at Dec. 31, 1940, the following proportions of persons on the Dispensary Register were actually living within their respective boroughs: Finsbury, 94.5%; Islington, approximately 90%; Stepney, about 75%; Greenwich, 92%; Paddington, 73%. The balance are those who had evacuated themselves temporarily. There is reason to believe that these proportions are higher than that which the total population at that date bore to the pre-war population.

The statistics must also reflect to some extent the progressive recruitment of fit persons to the Forces. This selection also has the effect of increasing the proportion "unfit" in the residual population. On the other hand, recruiting boards have discovered some cases of active tuberculosis which otherwise would not have been diagnosed until the disease became more advanced.

Account must be taken of the aerial bombardment of 1940–1, with its concomitant physical and psychological strain and temporary overcrowding. It would be interesting to compare the experience of London with that of other much-bombed towns, but the necessary statistics are not available to us.

Part of the increases in the numbers of notifications of and deaths from tuberculosis can be attributed to reduced resistance to the disease and increased numbers of new cases diagnosed among Londoners who are patients in mental hospitals. The increase in the rate of occurrence of new cases among mental patients between 1938 and 1941 amounted to 0.12 per 1,000 of the total population of the County of London, and therefore, out of the rise of 43% in incidence, 9% is attributable to increased notifications in respect of mental patients. The increase, as such, has, however, been exaggerated by the fact that during 1941 more extensive measures of diagnosis were instituted in the mental hospitals and that therefore some of the notifications in 1941 related to patients who had been tuberculous for some time. With regard to mortality there is evidence that the proportion of all deaths of mental patients which are associated with active tubercle appears to have risen. An investigation is being made to ascertain the extent of increased incidence of tuberculosis in mental hospitals.

Finally there is the important factor of increased employment. Since Dunkirk there has been no respite from the heavy demands of war industry. Hours of work have been long. Travelling conditions have often been bad. Moreover, in wartime many less healthy persons obtain employment who would not in peacetime successfully compete in the labour market. Many have taken up heavier types of employment; this, in the case of infected persons, might make all the difference between the quiescence and development of the disease. Generally, in considering the balance between input and output of energy of the human body it is possible that the prominence given to measures for improving nutrition has distracted attention from the output side of the equation.

The statistics of non-pulmonary tuberculosis throw light on the type of infection and on the efficacy of the sterilization or pasteurization of milk as a means of reducing the risk of infection. Most of the milk consumed in the Metropolis is pasteurized, and therefore the fact that abdominal infections have not increased in proportion to infections at other sites is of special significance. The disproportionate rise in non-abdominal infections indicates that while pasteurization has held back the spread of bovine infections the principal infecting source is human. In this respect the experience of Glasgow (*British Medical Journal*, 1941, **2**, 436) is similar.

The experience of London differs from that of Glasgow in two important respects: (1) The increase in the incidence of tuberculosis is greater in respect of children than in respect of adults; and (2) new cases of pulmonary tuberculosis increased more in adults than new cases of non-pulmonary disease. This fact, coupled with the evidence of site distribution for non-pulmonary forms of disease in children, suggests that contact and droplet infection has been an important feature in London It is difficult to assess the relative importance of decreased resistance to new or old-standing infections.

Summary

The effect of the conditions of war upon the trend of tuberculosis incidence in a densely populated and much-bombed urban area has been examined. The principal findings are:

1. As compared with 1938, there was in 1941 an increase of 43% in the rate of occurrence of new cases of pulmonary tuberculosis and of 15% in new cases of non-pulmonary tuberculosis. The pulmonary tuberculosis death rate increased over the same period by 72% and the non-pulmonary rate by 67%. These increases are much greater than for England and Wales as a whole.

2. The increase in the incidence of tuberculosis affected children much more than adults, particularly in the non-

pulmonary type, in which the increase was practically confined to the "under-fifteens" (except the increase of tuberculous meningitis, which extended to adult ages).

3. At ages over 25 males have been more affected than females. Below 25 it appears that, with the non-pulmonary type, females have been more affected than males, but with pulmonary tuberculosis at these younger ages there is no conclusive evidence that one sex has been more affected than the other.

4. The increase in non-pulmonary tuberculosis has occurred almost equally in all the principal sites, except in abdominal tuberculosis, in which the increase was significantly lower.

5. New cases of pulmonary tuberculosis increased more in adults than new cases of the non-pulmonary disease. This fact, coupled with the evidence of site distribution for non-pulmonary forms in children, suggests that contact and droplet infection has been an important feature in London.

6. There is evidence both that pasteurization of milk has held back the spread of bovine infections and that the principal infecting source is human.

7. Factors influencing the incidence of tuberculosis include changes in the age and sex distribution of the population as a result of evacuation and of recruitment to the Forces, the strain and overcrowding resulting from bombing, fatigue and lack of rest, restriction of diet, and, on the other hand, increased employment and financial resources for those formerly on the verge of poverty. In mental hospitals the increased incidence is greater than in the population as a whole

WARTIME DERMATOLOGY

WITH A PLEA FOR ECONOMY

BY

R. WORKMAN CARSLAW, M.D.

Surgeon-Lieutenant, R.N.V.R., Assistant Physician for Diseases of the Skin, Victoria Infirmary, Glasgow

The treatment of diseases of the skin in peacetime is considered of little importance and of no urgency, as the sufferers are said never to be cured nor yet to die. In recent years, however, treatment has advanced considerably and so have teaching and hospital facilities. Only when the whole of the available working power of the country is mobilized is the crippling effect of diseases of the skin fully realized, and their treatment assumes added importance in wartime medicine (Vickers, 1940).

In the Services it was soon found that many man-hours could be lost through trivial skin complaints. At sea about 50% of the daily attendances at the sick bay are for skin complaints. This takes up time and space and medical stores, of which only a limited stock can be carried. Scabies has become rife in the large centres of population, and as a result its prevalence has increased in the Navy. Recent experience of dermatology in the Naval Medical Service has brought several facts forcibly to my attention, and these are expressed in the following notes.

Material

The survey covers a period of two and a half years, which began one month before the opening of hostilities. This period falls naturally into three parts—namely, six months at sea, eighteen months ashore, and a second period of six months at sea.

The first part is the experience of six months afloat in cold or extremely cold conditions with a personnel of approximately 500 men. During this time there was little contact with centres of population, and the food was good, with a reasonable amount of fresh fruit and vegetables. The accommodation was crowded and the hours of darkness long, but the general health remained good. The second part is the experience of the skin department of a large naval hospital at home. Here there was accommodation for 28 in-patients, and out-patients were seen by consultation. The cases were drawn from all three Services in the area and the ships based on the port. A small number of foreign invalids were received. The third part is the experience of six months afloat in tropical conditions with a personnel of approximately 1,600 men. Little contact was made with centres of population, and fresh food was intermittently available. The accommodation was satisfactory and the period of daylight 12 hours. The general health was also satisfactory.

Circumstances peculiar to the Service are found to be on both the credit and the debit side. The discipline enables the medical officer to obtain greater control over treatment, but the exigencies of the Service may interfere with it. The population is entirely male afloat, and largely so ashore, while children are not included. The standard of physical fitness is above the average of the general population. The nursing facilities are limited. The number of attendants is small, and their training is short judged by civil nursing standards. Accommodation is limited, and isolation difficult except in the hospitals. At sea, facilities for dispensing are often poor and replacement of medical stores is difficult; rapid changes in climatic conditions are encountered, and the laundry is often overtaxed. Ashore, the personnel are apt to move from one area to another without warning.

Restrictions imposed by War Conditions.—Economy in all things is of paramount importance in wartime. Loss of man-hours is a matter for grave concern, and those affected with skin lesions must continue their normal work wherever possible If it is necessary to take a patient off work his sick period must be kept to a minimum. Economy in various drugs is an essential part of the national economy, and where an alternative exists the inferior drug may have to be employed in the national interest. Where alternative treatments are possible, that which combines effectiveness with economy should be chosen without regard for the personal experience or preference of the medical officer or patient. The nursing staff is relatively reduced in number and the training period for probationers is shortened. The standard of physical fitness is lower than in peacetime. The necessity for black-out, with impaired ventilation and the wearing of gas masks, must have a deleterious effect on skin conditions.

The Cases

First Part.—During this period few skin cases were encountered. These consisted of a number of cases of impetigo and scabies and several cases of dermatitis of the hands, apparently due to change from civil to Service occupation.

Second Part.—During this period 1,149 cases were seen—652 as in-patients and 497 in consultation. There were a large variety of conditions, but only the more common ones are shown in Table I.

TABLE I.

Disease	In-patient	Out-patient	Total
Dermatitis from all causes	31·6%	30·7%	31%
Seborrhoeic dermatitis	8·5%	8%	8%
Occupational dermatitis	4%	7·6%	5·5%
Dermatitis medicamentosa	3·7%	1·5%	3%
Scabies	27%	9%	18%
Impetigo	16%	4%	10%
Mycosis*	8%	9%	8·4%

* Including tinea pedis, tinea cruris, and tinea circinata.

Third Part.—During this period 349 cases were treated. As these cases were seen afloat, they were kept under observation up till the time of writing—i.e., two months after the end of the period. Only those conditions with an incidence of over 5% are shown. They were: mycosis, 56%, scabies, 15%: miliaria rubra, 13.5%, and impetigo, 8%

Treatment

Four conditions make up 67.4% of the cases in Part 2, and four conditions make up 92.5% in Part 3. Three conditions are common to both—namely, scabies, impetigo, and mycosis—the remaining two being dermatitis from all causes and miliaria rubra. Briefly, the treatment used in those five conditions was as follows:

Scabies.—During Part 2 an emulsion of benzyl benzoate was employed. The formula and procedure for this emulsion were described in a previous paper (Carslaw and Swenarton, 1941). In Part 3 this emulsion was unobtainable, in the early months sulphur ointment (*B.P.*) being used, and later the benzyl benzoate mixture with soft soap and spirit. A course of treatment in each case consisted of three applications in three days, with a hot bath before treatment. Disinfestation of all clothing was carried out. The results are shown in Table II. The 4 cases which failed to respond to sulphur treatment responded later to a course of benzyl benzoate. The minimum time of observation after treatment has been 2 months.

Table II

Treatment	1 Course	2 Courses	Failures	Total
Benzyl benzoate mixture . .	27	4	—	31
Sulphur ointment	18	1	4	23

Impetigo.—The treatment for impetigo in Part 2—i.e., in the home climate—was sulphanilamide ointment followed by a brilliant-green stearate paste. This treatment was described in a previous paper (Carslaw and Swenarton, 1941), and proved successful. In the Tropics the paste was not stiff enough, and the sulphanilamide ointment was contraindicated because of the ointment base. The routine treatment in Part 3 was swabbing with lotio hydrarg. perchlor. 1 in 1,500, followed by the application of lotio calaminae. This treatment was carried out twice a day. Firm dry crusts were thus formed which on separation left a healed surface. By this means 27 cases were treated without a failure, and the patients were able to carry out their full duties. The cases of impetigo occurring in the Tropics were of a mild type.

Dermatitis.—This term is taken to cover allergic dermatitis, seborrhoeic dermatitis, dermatitis venenata, dermatitis medicamentosa, and occupational dermatitis. The treatment varied to a certain extent with the aetiology, but was chiefly influenced by the histology and the need for economy. The dermatitis might be exudative, inflammatory, parakeratotic, or lichenified, and the treatment was normally lotio plumbi (*B.P.*), ichthyol 10% in water, aqueous gentian violet 1%, lotio calaminae with tar, or tar 5% in zinc ointment. The ointment base was used only if there was considerable scaling.

Miliaria Rubra.—This condition was almost universal in the Tropics, and only the more severe cases could be given treatment. This consisted of lotio calaminae 2 parts, spirit 1 part, to which was added carbolic acid 1% and in some cases menthol 1%.

Mycosis.—Ingram (1942) recently drew attention to the increasing incidence of ringworm infection of groins and toes in the Services. This is borne out by the fact that there were 196 cases of ringworm infection in Part 3—i.e., 56% of all cases. Andrews (1938) states that it is not the fungicide but the method of application that is of importance, and gives a list of fungicides. When it was realized that mycotic infections would be numerous the fungicides carried in the ship were checked and a plan devised. The first cases were treated with tinct. iod. mitis for three days, followed by salicylic acid 5% in spirit for four days, this course being repeated as often as necessary. Salicylic acid 5% in spirit, increasing up to 20% for some cases, was next employed. The limited stock of chrysarobin ointment (*U.S.P.*) was brought into use, and later on gentian violet 1% in spirit was pressed into service. The last was found to be impracticable on account of the staining of clothing, and so thymol 5% in spirit was tried. As thymol proved unsatisfactory a return was made to tinct. iod. mitis twice a day without salicylic acid. Carbolic acid 1% in sulphur ointment (*B.P.*) was given a short trial, and mercuric iodide in spirit was used for 3 cases but was found to cause second-degree burning and destruction of tissue. Table III shows the results achieved with the various treatments. It must be remembered that the number of cases in each group was partly governed by the quantity of the drug carried.

Table III

Treatment	Duration of Treatment in Days			Failed	Total Cases
	1–7	8–14	15+		
	%	%	%	%	
Chrysarobin oint.	78	11	—	11	36
Tinc. iod. mitis . .	37	31	20	12	51
Gentian violet 1%	67	20	—	13	15
Tinc. iod. mitis and ac. salicylic. 5%	13	22	52	13	23
Ac. salicylic. 5–20%	26	26	15	33	39
Thymol	10·5	10·5	21	58	19
Ac. carbol. 1% and sulphur oint. . .	—	30	—	70	10
Mercuric iodide . .	100	—	—	0	3

It will be seen that chrysarobin ointment treatment was the most successful, followed by gentian violet 1% in spirit and then tinct. iod. mitis. A 5% solution of chrysarobin in water was found to be at least as efficacious as the ointment, but only 2 drachms of dry chrysarobin was available. The extent of the ringworm infection was remarkable, 75 cases having lesions on the body in addition to those on the feet or groins. In one case large patches of mycosis extended over almost the whole of the bathing-drawers area, and in another practically the entire back was covered by a single patch. The 58 cases of infection of the feet were controlled by the application of gentian violet lotion 1%, and occasionally Whitfield's ointment was applied if the dry scaling became marked. This treatment was found to be successful, and although it is not suggested that the cases were permanently cured, the men were able to continue with their work and were free from symptoms. The fungus was distributed on the body as follows: tinea cruris and circinata, 68 cases; tinea cruris only, 62; tinea pedis only, 40; tinea cruris and pedis, 11; tinea circinata only, 8; tinea cruris, circinata, and pedis, 6; tinea circinata and pedis, 1 case.

Discussion

I feel that the treatment of skin diseases has been too conservative, shrouded in mystery, and bogged in ointment. Textbooks of dermatology are of little use to the Service medical officer in wartime, as it is often totally impossible to carry out the treatment recommended; and, furthermore, a textbook for temperate climates is useless for the Tropics. I think the following are the salient points in Service wartime dermatology: (1) economy is of national importance; (2) the bulk of medical stores must be kept small; (3) simplicity and, where possible, standardization ease the burden of an overtaxed nursing staff; (4) early diagnosis and treatment saves loss of man-hours.

Two treatments described in this paper are contrary to the policy of economy advocated. Chrysarobin ointment was used, not the aqueous solution; and a mercury lotion was employed in the treatment of impetigo. The reason was that the ointment and the mercury were carried in the ship, though it would have been an economy if they had been replaced by the powder and a larger stock of aniline dyes.

Economy has been stressed recently in many articles in the medical press. Brain (1941) states: "No mention has been made of mercury because, although of value, it is more essential to the national economy in war industries." This statement was made in discussing the treatment of impetigo.

Ointments could, it is felt, be largely discarded, particularly in summer and in hot climates; mercury be replaced by aniline dyes; and starch poultices be put out of production. Dressings are often changed four-hourly, but this may retard healing, and a twice-daily dressing is normally sufficient and in many cases not even necessary. Dressings should always be as light as possible, no wool or lint being used. Brain (1941) states that an ointment in the treatment of impetigo is inadvisable, as a film of grease retains exudates and sweat, which encourage the growth of organisms and irritate the follicles. Both Conybeare (1940) and Brain stress that a dry intact stratum corneum is Nature's defence against skin infection. The saving in ointment means a conservation of the all-important fats. Those drugs which can be carried in a powder or crystalline form save space, as they are commonly used in weak aqueous solutions. In this connexion chrysarobin powder and gentian-violet crystals should always be carried in this form and never as an ointment or in solution. Crude coal-tar should be substituted for a prepared tar.

The best results are attained by the use of a comparatively small number of remedies (Conybeare, 1940), and simplicity saves the time of nursing and dispensing staffs. Early diagnosis, and therefore the early institution of treatment, means a smaller area to treat and a saving of stores and time lost.

In many ways life has been made more simple by the introduction of rationing in domestic life, and a plea is made that the treatment of skin conditions could and should be simplified to conform with the national war effort.

Summary

A survey is made of 1,498 skin cases seen in the Royal Navy in wartime.

It is shown that five conditions cause the majority of skin casualties in the Navy. The treatment used for those five conditions in two and a half years of wartime dermatology is very briefly described. Emphasis is placed on the treatment of mycosis—for which chrysarobin is recommended—as those cases were unusually severe and numerous.

The difference between the civil practice of dermatology and dermatology in the Service is mentioned and the added difficulties of war conditions are noted.

A plea is made for greater economy and simplicity in the treatment of skin conditions.

I am indebted to Surg. Cmdr. Patrick for permission to publish this paper.

LIGATURE OF INNOMINATE ARTERY FOR RIGHT SUBCLAVIAN ANEURYSM: END-RESULT

BY

Sir W. I. de C. WHEELER, M.Ch.(Hon.), F.A.C.S.(Hon.), F.R.C.S.I.
Temporary Surgeon Rear-Admiral

In the case of which the end-result is here recorded, the innominate artery was ligatured in Dublin in May, 1932, for right subclavian aneurysm. The patient died 8 years and 4 months later, in Sept., 1940, presumably from rupture of an aneurysmal sac. No details could be obtained. Death was sudden and unexpected.

Three previous cases have been reported from Dublin; these occurred in the days before aseptic surgery. Coppinger of the Mater Misericordiae Hospital was the first surgeon in Europe to tie successfully the innominate artery for subclavian aneurysm (1893). Sixteen months after operation "the aneurysm was represented only by a small movable and hard filbert-sized tumour." In this case the carotid artery was divided between two ligatures. Thomson of the Richmond Hospital lost a case from secondary haemorrhage on the forty-second day, and O'Grady of Mercer's Hospital reported a case in which the patient died of "apoplexy" on the day following operation. In this instance the carotid artery also was tied. Ligature of the innominate artery remains a rare procedure. Up to and including the year 1922 there were 57 cases on record with 19 recoveries (Ballance, 1921). Rundle (1937) adds 5 subsequent cases. I have been unable to obtain the figures for recent years, but, judging by the paucity of cases in the past, it may be assumed that the total number to date does not exceed the round figure of 70. It is not the purpose of this communication to discuss the merits or drawbacks of the various surgical procedures. Whatever operation is employed for aneurysm of the aorta or any of its main branches the life of the patient may be prolonged, but he remains in a condition of perpetual jeopardy, and seldom survives for many years. The longest survival period after ligature of the innominate artery which I could find in the records is 10 years (Smyth of New Orleans, quoted by Erichsen, 1895). After ligature of the subclavian and common carotid for innominate aneurysm a patient was alive 18 years after operation (Baldwin's case, mentioned by Rundle). I have had one case of abdominal aneurysm in which the patient lived for the same period after the introduction of Colt's wires. These cases are, however, the exception; the majority of "cures" and "successes" are recorded when only a few weeks or months have elapsed after operation. Guidance as to prognosis is difficult to obtain from published cases: exaggerated claims are made long before real results could be estimated. Post-mortem specimens obtained shortly after operation are not convincing evidence of "cure" unless death can be attributed to a condition neither directly nor indirectly concerned with the aneurysm. Even when this can be proved, it must be remembered that most of the patients who survived for many years eventually died of a secondary dilatation of the artery or a recurrence of the original aneursym. The fact is, operation is palliative only, although a few surprisingly good results are on record.

In the original report of the case under review it was pointed out that the ideal operation for subclavian aneurysm is proximal and distal ligature with excision of the sac. As there was an apparent "cure" after ligature of the innominate artery, a contemplated second-stage operation (i.e., an attempt to ligature the distal arteries and excise the sac) was abandoned.

History of the Case

The patient, approximately 35 years of age, was wounded in France in 1915. On examination in 1932 a portion of a bullet could be seen by *x* rays deep to the insertion of the right sterno-mastoid muscle. There was a pulsating swelling the size of a duck's egg above the right clavicle. The right recurrent laryngeal nerve was paralysed, but, apart from this, there was a striking absence of the more usual clinical signs. The radial pulse was not affected, the blood pressure was the same on both sides, there was no bruit, and expansile pulsation could not be detected. The Wassermann reaction was negative.

It was hoped that ligature of the subclavian artery behind the scalenus anticus muscle would be possible and that, later, distal ligature and excision of the sac could be accomplished. The clavicle was divided in two places so that the central portion with its pectoral attachments could be turned downwards on the chest (Moynihan). The aneurysm in this manner was laid bare and the bullet removed. The external and internal jugular veins were found obstructed and distended. The suprascapular and transversalis colli arteries were seen lying transversely across the tumour. The scalenus anticus muscle, as such, had disappeared and the phrenic nerve was not located. The sac clearly extended to the bifurcation of the innominate artery, and in consequence proximal ligature of the subclavian artery was impossible.

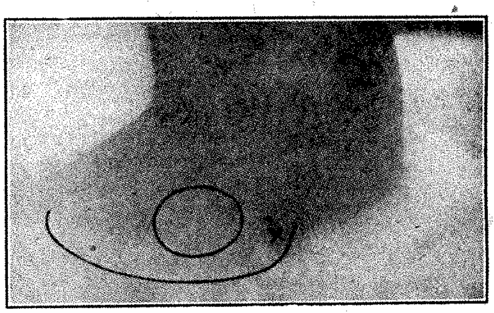

Fig. 1.—Subclavian aneurysm. The position of the tumour and the line of incision are shown. × marks the position of the bullet.

Fig. 2.—Subclavian aneurysm treated by ligature of the innominate artery. A, Transversalis colli artery. B, External jugular vein. C, Suprascapular artery. D, Divided sternum and sterno-clavicular joint retracted upwards. E, Hook retractor just above attachment of first rib to sternum. F, Innominate artery. Inset shows ligatures applied proximal and distal to thyroidea ima branch.

There was ample exposure for exploration in detail, but ligature of the innominate artery required more room if rough handling of the sac was to be avoided. The portion of the manubrium sterni which is closely related to the sterno-clavicular joint was cleared back and front and divided with a chisel. There was no interference with the first costal cartilage. The divided portion of the sternum carrying the sterno-clavicular joint and the inner portion of the clavicle was retracted upwards and to the left. The innominate artery was now seen clearly in its entire length (2 inches). The veins were not visible, the pleura caused no embarrassment, and the nerves remained hidden. The thyroidea ima branch was present. Two No. 2 catgut ligatures were passed round the main artery distal to this small branch (Figs. 1 and 2). They were tied slowly and gently to avoid, if possible, rupture of the coats. Pulsation in the aneurysm ceased and the radial pulse disappeared. Each pulsation of the artery now had the appearance of a sledge-hammer blow on the point of occlusion. For safety a third ligature was placed nearer the aorta. The thyroidea ima branch was ligatured with fine silk.

The divided clavicle and portion of sternum were replaced, the former being held in position by sutures through drill-holes in the bone. In three days the radial pulse reappeared, and in a week it was of normal volume. Six weeks later some faint pulsation could be felt in a very small swelling at the site of the original sac. Four months after operation there was no pulsation. Six years later the case was examined by Mr. R. A. Stoney of Dublin. He kindly reported that the patient appeared quite well. A small lump could be felt, but there was no pulsation or thrill.

Comment

Ligature of the innominate artery is not a difficult operation provided the exposure is adequate. Exploration, and the clearing of the deep surface of the manubrium sterni, are greatly facilitated by turning down the middle portion of the clavicle. In most cases I think this should be the first major step in the operation.

If ligature of the innominate is seen to be necessary a portion of the sternum should be divided and retracted upwards with the inner end of the clavicle. This can be accomplished without division of the first costal cartilage.

CEREBROSPINAL FEVER

A REVIEW OF 500 CASES TREATED BY CHEMOTHERAPY WITHOUT INTRATHECAL SERUM

BY

G. EMRYS HARRIES, M.B.Lond., D.P.H.

Medical Superintendent, City Isolation Hospital, Canton, Cardiff; Lecturer in Infectious Diseases, Welsh National School of Medicine

For the purpose of comparison of the results of the various forms of treatment Table I gives the case-mortality figures for cerebrospinal fever patients admitted to this hospital during the last 10 years.

TABLE I

	Intrathecal Serum					Sulphanilamide and Intrathecal Serum	Sulphapyridine and Iatrathecal Serum	Sulphapyridine or Sulphathiazole without Intrathecal Serum

* Only first 20 cases (1 death) are included in the present series.

Within a period of two years and two months (Jan., 1940, to Feb., 1942) 500 patients admitted to the Cardiff City Isolation Hospital suffering from cerebrospinal fever were treated by chemotherapy without intrathecal antimeningococcal serum. As this is one of the largest series of cases of cerebrospinal fever ever so treated, a brief analysis, together with a few observations, may be of general interest. The ages ranged from an infant of 6 weeks, who made a complete recovery (examined 12 months after discharge), to a fatal case in a person aged 70 years. All cases of cerebrospinal fever which were admitted during the period are included, even those that were moribund and died within a few minutes of admission. The total number of deaths was 43, furnishing a gross mortality rate for the whole series of 8.6%.

With a disease such as cerebrospinal fever, which has a fulminating form that often kills on the first day, a totally erroneous case-mortality rate is obtained if cases that end fatally within 24 hours of admission are excluded. Were such a procedure adopted in this series the case-mortality rate would have been recorded as only 4.8%.

Age and Sex Distribution

Table II gives the sex distribution and case-mortality rates of the various age groups.

TABLE II

Age Group	Males			Females			Total Cases		
	No.	Deaths	%	No.	Deaths	%	No.	Deaths	%
0–3 months	—	—	—	1	—	—	1	—	—
3–6 ,,	6	2	33·3	7	2	28·6	13	4	30·8
6–12 ,,	16	1	6·2	11	1	9·1	27	2	7·4
1–5 years	62	4	6·4	53	3	5·6	115	7	6·1
5–10 ,,	27	1	3·7	29	3	10·3	56	4	7·1
10–15 ,,	27	2	7·4	24	—	—	51	2	3·9

20–25 ,,	22	—	—	11	1	9·1	33	1	3·0
25–30 ,,	19	1	5·3	5	—	—	24	1	4·2
30–35 ,,	20	2	10·0	21	3	14·3	41	5	12·2
35–40 ,,	10	1	10·0	6	—	—	16	1	6·2
40–45 ,,	10	3	30·0	7	2	28·6	17	5	29·4
45–50 ,,	5	1	20·0	5	—	—	10	1	10·0
50–55 ,,	4	—	—	8	2	25·0	12	2	16·6
55–60 ,,	5	2	40·0	—	—	—	5	2	40·0
60–65 ,,	4	2	50·0	—	—	—	4	2	50·0
65–70 ,,	2	2	100·0	1	1	100·0	3	3	100·0
70–75 ,,	—	—	—	1	1	100·0	1	1	100·0
All Ages ..	289	24	8·3	211	19	9·0	500	43	8·6

It is noteworthy that in the favourable age group 10 to 30 years there were 179 cases with but 4 deaths, giving a case-mortality rate of only 2.2%. In the subgroup 15 to 25 years there were 104 cases with but 1 death—i.e., a case mortality of even less than 1% ; whereas among four patients of over 65 years there was no instance of recovery. From this will be seen the importance of furnishing the age distribution for any case-mortality figures for cerebrospinal fever. There were 44 non-civilians in this series, all of whom recovered, probably on account of their general fitness, favourable age-grouping, and early admission to hospital for treatment.

Proposed Classification

From my experience of cerebrospinal fever I believe the following classification covers all types of cases.

1. *The Meningococcal Septicaemic Type.*—(*a*) Acute, fulminating, exhibiting the Waterhouse-Friderichsen syndrome with adrenal haemorrhages, purpuric eruptions, pallor, and collapse ; such patients frequently die before development of meningitis. (*b*) Chronic meningococcaemia with intermittent periods of pyrexia, usually petechiae and arthritis, occasionally lesions resembling erythema nodosum, and rarely maculo-papular eruptions. This type of case may recover spontaneously or proceed to meningitic involvement unless adequately treated with chemotherapy.

2. *The Meningitic Type.*—(*a*) Acute ; (*b*) subacute ; (*c*) chronic (including the post-basic variety of Gee and Barlow in infants).

3. *The Encephalitic Type.*—Though every case of meningitis is essentially one of meningo-cortico-encephalitis, cases undoubtedly occur, fortunately rare, in which lesions are found deep in the nervous tissue. In fact, at necropsy on one of my cases meningococci could be demonstrated in the internal capsule. These cases are difficult of clinical recognition, but the

brain-stem appears often to be involved with signs of bulbar palsy, especially pharyngeal paralysis and severe respiratory distress, but at the onset no pulmonary lesions are detectable. This type of case is usually fatal.

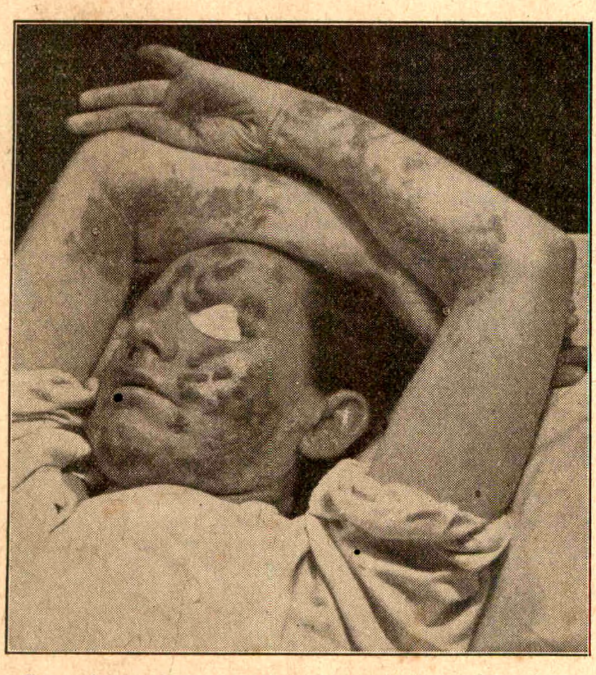
Special Diagnostic Features

It was observed that slight nuchal rigidity was a far more constant and early finding than Kernig's sign. Photophobia was conspicuous mainly by its absence. Contrary to the general impression regarding infants, a bulging anterior fontanelle was uncommon, but, rather, a depressed fontanelle was often present, being probably due to vomiting and consequent dehydration. The abdominal, knee, and plantar reflexes appeared to have no diagnostic significance except that the abdominal reflexes were almost invariably absent in those cases bordering on coma.

In only three instances did more than one case occur in the same household, but in one household there were 3 cases.

Eruptions and Complications

Purpuric eruptions, generally petechiae which appeared on the first or second day of disease, were present in 39% of cases, usually occurring in the more severe ones; but extensive purpuric eruptions were occasionally found in comparatively mild cases. Herpes—generally on the face, around the lips, though sometimes occurring in unusual situations, such as on the digits or palms of the hands—was present in 33% of the cases, usually towards the end of the first week of the disease. Unlike pneumonia, the presence of herpes was of no prognostic import. Both herpes and purpuric eruptions occurred in an additional 16% of the cases. The accompanying photograph shows an extensive herpetiform eruption in a woman aged 31, who had an attack of but moderate severity.



Severe herpes in a case of cerebrospinal fever of moderate severity: complete recovery.

The following were the main complications: Transient strabismus, 77; bronchopneumonia, 12 (usually confirmed post mortem); arthritis, 29 (mainly the larger joints); deafness, temporary and partial 11, total and permanent 7; transient albuminuria, 91; conjunctivitis or iridocyclitis, 17; transient paresis of arms, 3; temporary facial paralysis, 10; transient ptosis, 8; transient hemiplegia, 1; temporary mental derangement, persisting well into convalescence, 4; hydrocephalus, 5; dysphagia, due to severe neck retraction, 2; transient nystagmus, 2; orchitis, 1.

Differential Diagnosis

The following cases were erroneously admitted as suffering from cerebrospinal fever; Tuberculous meningitis, 25; pneumococcal meningitis, 8; aseptic meningitis, 10; influenzal meningitis, 2; subarachnoid haemorrhage, 9; poliomyelitis, 16; polio-encephalitis, 8; influenza, 58; lobar pneumonia, 8; bronchopneumonia, 14; miliary tuberculosis, 1; cerebral abscess, 1; cerebral tumour, 1; infective endocarditis, 1; frontal sinusitis, 1; tonsillitis, 14; otitis media, 2; bronchitis, 12; glandular fever, 1; tetanus, 1; rheumatic fever, 2; dysentery, 2; diphtheria, 1; pyelitis, 1; adenitis, 1; pleurisy, 3; gastritis, 1; measles and encephalitis, 1; whooping-cough and bronchopneumonia, 1; mastoiditis, 1; rubella and rheumatism, 1; paratyphoid B fever, 5; fractured base of skull, 1; uraemia, 3; catarrhal jaundice, 1; septic arthritis, 1; diphtheria, 2.

Conversely, cases notified as the following proved to be cerebrospinal fever: Polio-encephalitis, 1; poliomyelitis, 1; diphtheria, 2; typhoid fever, 1.

Chemotherapy

Sulphapyridine was employed in 471 cases and sulphathiazole in the remaining 29. Sulphathiazole appeared to be equally effective in promoting recovery and was less prone to produce nausea and vomiting.

Two grammes (4 tablets) was given by mouth on admission and repeated in 4 hours' time; then 1 g. 4-hourly for the next 72 hours; then 0.5 g. 6-hourly for a further 3 days. After the first 250 cases the dosage was increased to 2 g. 4-hourly for 4 doses and then 1 g. 4-hourly for 96 hours, followed by 0.5 g. 6-hourly for a further 3 days. The increased dosage was found to have a slight effect in diminishing recurrences and septic complications such as arthritis. Children under 12 years received half the adult dosage, and infants under 12 months a quarter. In all, 1,935 lumbar punctures were performed without any untoward effects—an average of 4 for each patient. No general anaesthetic was administered. Apart from relieving headache, the reduced intracranial pressure was considered less damaging to the nervous tissue. Incidentally, the cerebrospinal fluid furnished a satisfactory guide to the progress of the disease. No case was regarded as out of danger if the sugar had not returned to normal. Only 6 ventricular and 5 cisternal punctures were considered necessary. If the patient was comatose the tablets were crushed and given in nasal feeds. If vomiting occurred after ingestion of the drug or the patient were delirious and nasal feeding were difficult, the sodium salt of sulphapyridine was given in the earlier cases by intramuscular injections; but as sloughing often ensued in spite of care, this practice was discontinued and the sodium salt in equivalent doses was injected intravenously with three times its volume of normal saline. In severe cases, or if there were much dehydration, the sodium salt of sulphapyridine was given intravenously in about 0.5 to 1 litre or more of normal saline in 5% glucose solution by the vacoliter drip method.

Only one patient in the whole series received serum intrathecally. This was a woman aged 40 who had a fatal relapse after having been free from symptoms for 6 weeks after the cerebrospinal fluid had returned to normal. During her relapse chemotherapy appeared to have no effect, and no improvement followed the intrathecal serum, but there was slight temporary improvement after an intrathecal injection of her own blood serum. Two children, both aged 1 year, had second attacks after intervals of 2 months and 3 months respectively. In one instance the organism was of the same group in both attacks, but in the other case the organism could not be cultured on the first admission. The second attacks responded well to chemotherapy.

Fluids were pushed in all cases, as, to my mind, dehydration can contribute materially to a fatal issue. Furthermore, the giving of adequate fluids probably lessens the incidence of haematuria due to the depositions of acetyl derivatives in the kidneys. One patient who ultimately recovered and had been in coma for 10 days was given fluids by nasal feeds at 4-hourly intervals during that period.

Since extensive haemorrhages are not infrequently found in the adrenals, in the acute septicaemic cases, 5% glucose-saline (0.5 to 1 litre) was given intravenously as indicated above, as sodium chloride and glucose are advocated in case of adrenal damage (McCance, 1936). In addition such cases received synthetic cortical extract (desoxycorticosterone acetate) intramuscularly, and in order to combat toxaemia 30 to 60 c.cm. of meningococcal antitoxin was also given intravenously in the glucose-saline. Several patients whose pulses were imperceptible on admission made complete recoveries on these lines. In all, 56 patients received glucose-saline intravenously, 34 serum intravenously, and 44 cortical extract intramuscularly. It was generally unnecessary to cut down on a vein for intravenous therapy. This new method of treating the acute fulminating septicaemic type of case was first introduced in this hospital early in 1940, and was published (Harries, 1940) in March of that year.

Patients who developed such complications as arthritis or iridocyclitis in convalescence received a second course of chemotherapy. All patients were given glucose freely, and even in the mildest purpuric cases a little common salt was added to the diet. If bromides were given as sedatives the sodium salt was administered rather than the potassium salt. Two patients who had neck retraction of such a degree as to prevent deglutition were successfully treated by the injection of a few cubic centimetres of novocain into the post-cervical muscles (Harries, 1936).

Sulphonamide Reactions.—These in the main were not alarming. Skin eruptions developed in 26 cases, jaundice in 4, marked cyanosis in 14, and transient haematuria in 3. No case developed agranulocytosis. One child, however, died from suppression of urine, probably due to renal damage; but permission for necropsy was not obtained.

No person in attendance contracted the disease. No masks were worn, as I believe the wearing of these predisposes to nasopharyngeal congestion and catarrh, which probably lowers the resistance of the mucous membrane. It is likely that infection of a healthy nasopharynx produces a temporary carrier state, with subsequent immunity. The giving of small prophylactic doses of sulphonamides in suspected cases had no effect on the meningococci except that the organisms appeared to be rendered drugfast, and large doses administered later were then less effective.

Bacteriological Investigations.—Morphological meningococci were found in 465 cases, or 93%. Cultures were obtained in 214 cases; of these 93% belonged to Group 1 and 3.7% to Group 2, while 3.3% were inagglutinable. Clinically, the various strains seemed to be of equal virulence.

Summary

A series of 500 cerebrospinal fever cases is recorded, with a gross mortality rate of 8.6%.

An age-distribution table indicates the most favourable age group as 15 to 25 years, with 104 cases and a case-mortality rate of just under 1%.

A suggested classification of all forms of cerebrospinal fever is given.

A new treatment for the acute fulminating septicaemic type is described.

Of the strains of the meningococci cultured 93% belonged to Group 1.

My thanks are due to Dr. Allison, who confirmed our bacteriological findings and who typed the organisms; to Prof. Duguid and Dr. Boissard for post-mortem examinations; and to Drs. Murphy, T. Thomas, Herapath, Lennox, Evans, and Garfield, quondam resident medical officers at this hospital, for their assistance in the treatment of the cases.

W. L. Downing (*J. Iowa State med. Soc.*, 1941, **31**, 538), who records 11 cases in persons aged from 24 to 67, 4 of which were fatal, states that acute pancreatic necrosis is still an unsolved disease. When the diagnosis is doubtful, early exploration should be performed to avoid overlooking perforated peptic ulcer or other emergencies. If acute pancreatitis is found, and disease of the biliary tract is present, cholecystotomy or choledochotomy, or occasionally cholecystectomy, is indicated. Operation should be avoided in the hyperacute type. If the diagnosis is certain, conservative measures should be used. Early operation is advisable in all patients with acute or chronic cholecystitis to avoid the complication of acute pancreatitis.

THE MANGLED FOREARM

TREATMENT IN A SKELETON SPLINT WITH FIXED SKELETAL TRACTION

BY

DAVID BROWN, M.Ch.(Orth.), F.R.C.S.Ed.
Honorary Orthopaedic Surgeon, Royal Infirmary, and Children's Hospital, Sunderland

In a compound fracture of the forearm, in which the bones are shattered and there are extensive lacerations, a complex problem in immobilization results. Given good fortune, an ordinary plaster may prove very satisfactory; yet one can remember several cases in which removal of a plaster became an urgent necessity to allow further surgical treatment. The result was that redisplacement of the bones took place and the sepsis gained nothing from the loss of immobilization.

I have found the following method very useful in these severe cases. The advantages are that there is no danger of circulatory failure due to a tight plaster and that the wounds can be fully inspected without disturbing the immobilization. The wound toilet needs no lengthy description except to emphasize the importance of excising all non-viable muscle and of providing a perfect drainage system if one feels that the wound is still contaminated even after excision.

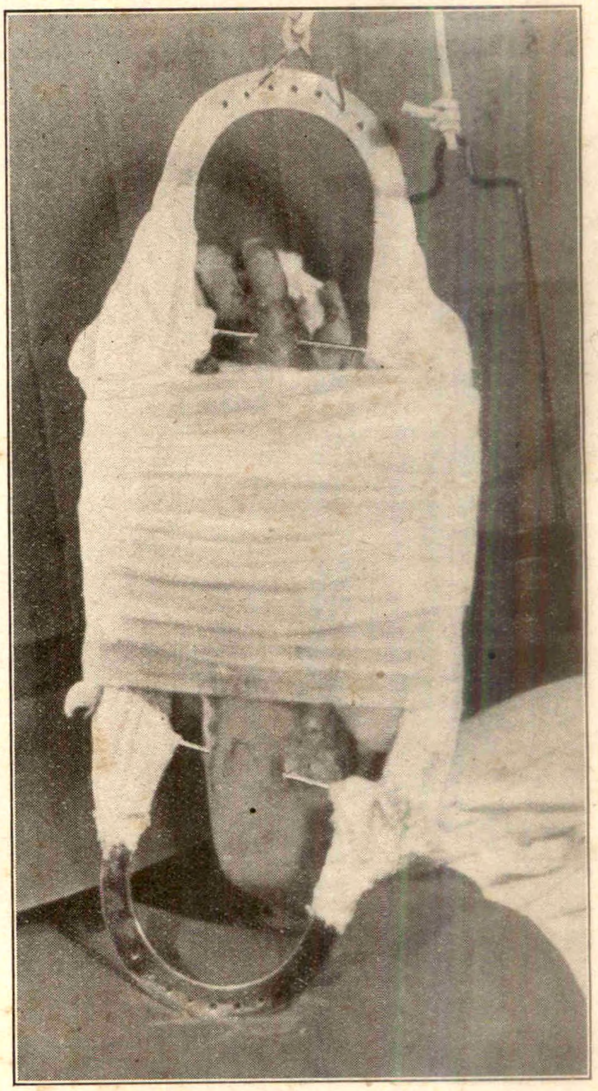

FIG. 1.—Posterior view. Note that the Kirschner wire which transfixes the metacarpal does not interfere with movements of the thumb or pierce any of the extensor tendons.

Method

After the wound toilet is complete a fine Kirschner wire is inserted obliquely across the back of the radial border of the second metacarpal, about an inch proximal to the head of the bone. A second wire is put through the subcutaneous border of the ulna 3 in. distal to the tip of the olecranon. A large stirrup is attached to each of these wires. An assistant now holds the arm suspended by the distal stirrup; the elbow is left at a right-angle. The proximal stirrup is allowed to hang down behind the olecranon. The weight of the arm, so suspended, is enough to produce full length, though alignment and rotations will need to be adjusted.

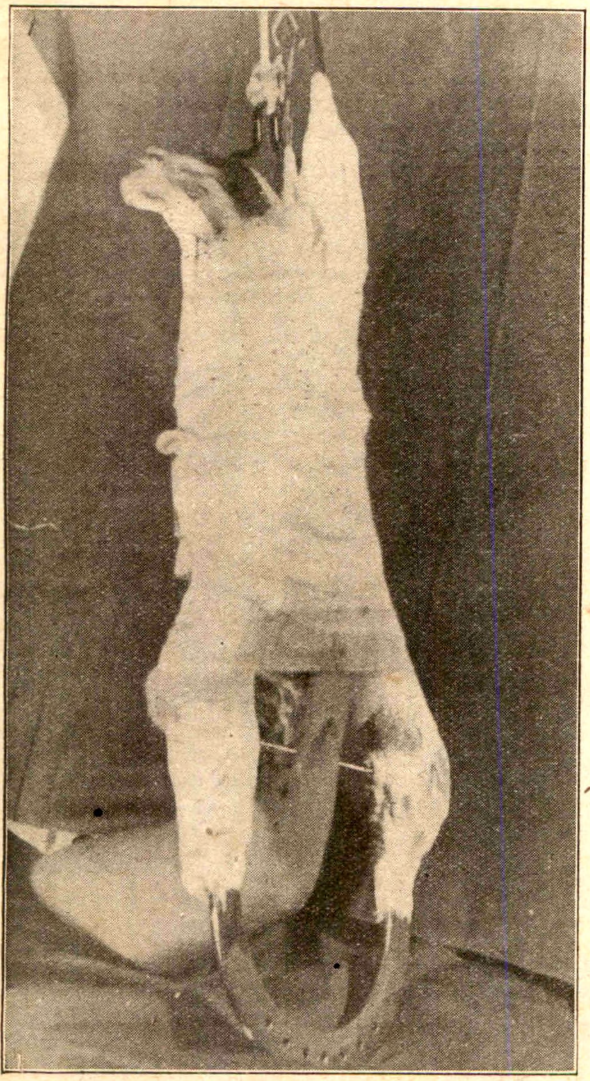

Fig. 2.—Lateral view.

While the arm is still held suspended the stirrups are connected together by two plaster ropes, each made of three 6-in. cellona bandages. Further adjustment of the fracture may be made while the ropes are drying. These ropes are parallel with the forearm, about 2 in. from it, and when dry convert the whole structure into a rigid skeleton splint with fixed skeletal traction. The dressing of the wounds is completed with a layer of wool and a bandage which encircles the side bars of the splint. The addition of extra wool anteriorly or posteriorly, combined with firm bandaging, will correct any tendency to a backward or forward bow. Finally a removable anterior plaster cock-up splint may be bandaged on to immobilize the fingers. When the patient returns to the ward the forearm is suspended vertically, with the elbow at a right-angle, and accurately counterbalanced with a weight. This is the best position to allow the swelling to subside, and puts least strain on the splint. Inspection of the wound or further surgical treatment can be carried out by removing the bandage which holds the dressing, and the arm need not be removed from its suspended position during the process.

Directly all active sepsis has disappeared the wires may be removed and a plaster applied. This can usually be done in two or three weeks. This point needs emphasis, since in the absence of definite indications the disadvantages of skeletal traction, such as wire-track sepsis and delayed union, will outweigh the advantages of this form of immobilization.

I am indebted to Dr. Geoffrey Robinson for his photographs of the splint.

Medical Memoranda

Notes on a Case of Death by Lightning

On Aug. 29, 1942, during a severe thunderstorm about 8.30 p.m., a farmer aged 54 was sheltering under a large bombing aeroplane lying in a grass field. A soldier about 200 yards away saw a "thunderbolt" fall, but did not trouble to investigate as there was no sign of fire afterwards. On the 30th, about 5.45 a.m., the corpse of the farmer was found lying supine under the wing close to the body of the aeroplane. Some camouflage netting, which stretched over the tail of the aeroplane, lay under the corpse. Also under the corpse and under the netting was a cross-piece of metal tubing about six inches long each way.

On the same day about 10.15 a.m. I examined the body, which had been taken to an outhouse near by. Rigor mortis was complete. The clothes, which were damp but not soaking, were removed. The cloth cap had a small hole in it. I could not see charring of the edges of the hole, though I looked carefully. Corresponding to the position of the hole in the cap there was a small hairless spot in the right parietal region looking like an abrasion. The face was congested, especially by the left cheek and left ear, where dark fluid blood oozed out of the pores of the skin. On each buttock over the ischial tuberosity there was a circular area about 1½ in. in diameter looking like a recent superficial burn. I could find no other signs of injury on external examination. The boots he was wearing were heavily shod with iron at heels and toes. His watch was still going. I think perhaps he was squatting or sitting on the ground, and the marks on scalp and buttocks show where the electric current passed.

Two fitters in charge of that particular bomber searched carefully inside and out, and found no sign of damage to the aeroplane, which is largely composed of metal. The aerial had a wire earthing it to a metal rod in the ground some 6 to 8 feet from where the corpse was found.

I do not know if similar deaths have been recorded. It is evidently not safe to shelter under an aeroplane in a thunderstorm. Perhaps it would have been quite safe inside the aeroplane, which was not damaged. I am a civilian practitioner, and record the case hoping it may be helpful to medical officers in charge of aerodromes.

Alfred V. Dill, M.D.

Tetanus in the Puerperium

Owing to the extreme rarity of cases of tetanus in the puerperium, it has been thought advisable, and important for statistical purposes, to record the following case.

Case History

A strong healthy woman aged 40 was delivered of a healthy child at a farm-holding on Jan. 21, 1942. Apart from difficulty of micturition during the third month, due to an impacted retroverted uterus, which was corrected without difficulty, her pregnancy ran a perfectly normal course. Her labour, too, which was supervised by the district nurse according to arrangement, was accomplished without any trouble, lasting some six hours. There was no tear of the perineum. The puerperium proceeded uneventfully until the tenth day, when the patient complained of a slight "stiffness of the neck." This was regarded by the nurse as a slight attack of fibrositis, but when, next day, the patient complained of stiffness of the jaw muscles and of inability to open her mouth properly or to swallow food and drink, the patient's doctor was sent for. On arrival he found the woman sitting up in bed in evident distress. There was a good deal of pain and stiffness in the neck, and trismus was very pronounced. Speech and swallowing had become impossible. At this time there were no spasms of the limbs or general convulsions. Facial symptoms were fairly well marked. Later there was partial intermission of the symptoms and the patient could make herself understood. This, however, was only temporary, and she was admitted to hospital on Jan. 31, 1942, where she was seen by a consultant physician. Later that same day, while being fed through a nasal tube, she developed severe spasms and died.

COMMENT

When it was realized that the case was obviously one of tetanus the question that immediately suggested itself was, How did the infection occur? Was it via the skin or the birth passages? It is perhaps significant, especially when it is remembered that the tetanus bacillus is usually present in cultivated ground and horse manure, that this case occurred in a farm-holding. In regard to the skin, careful inquiry failed to elicit any history of recent cuts or external wounds, and examination revealed no evidence of any recent scars. On the other hand one can quite conceive how infection would occur by the birth passages. Although the district nurse supervised the puerperium, it appears that on several occasions the patient "attended to herself." One can easily imagine some member of the family handing the patient the necessary utensils, bowl, wool, etc., and there is a temptation to conclude that infection occurred in this way. Against this possible explanation, however, are the post-mortem bacteriological findings. Necropsy showed no lesions except in the uterus, from which a small piece of adherent placenta was removed, and a very careful bacteriological investigation failed to reveal the presence of tetanus bacilli in any of the birth passages. Some were found in the bowel, but this, apparently, is not unusual in the adult gut. The skin seems the more probable route of infection, in spite of the absence of external evidence, and one can only suggest that some tiny prick or scratch may have healed over before the illness.

The 1940 report of the Royal College of Obstetricians and Gynaecologists contains the findings of a special committee set up to investigate the question of tetanus in relation to childbirth. The conclusion arrived at was that cotton-wool as commonly supplied by chemists often contained many organisms, among which the tetanus bacillus was occasionally found. This may provide another possible explanation of the source of infection, but in the absence of any definite findings, both in regard to the skin and to the birth passages, the mode of infection must remain "something of a mystery."

Reaction to Rubber-ended Stethoscope

The following case is recorded as an example of extreme sensitivity to rubber. I know of no other instance in which reaction has occurred after such short contact.

A power-loom overlooker aged 35 was referred to me by his doctor on Sept. 2, 1942. He gave a history of reacting to his suspenders—i.e., the small rubber pieces to which the buttons are attached—in the spring of 1941. He was then told to stop wearing suspenders, and the eruption gradually cleared. At Whitsuntide of this year he went for a holiday to the country, and took with him a pair of rubber Wellington boots for walking through the fields. He noticed as he was tramping along, wearing these boots, that his socks kept falling down, leaving a gap between socks and breeches. The same night a circular band eruption broke out corresponding to this area and, of course, he stopped wearing the boots. The reaction was a severe one, and it was on account of this that his doctor referred him to me.

The facts up to now merely demonstrate a case of rubber sensitivity. After I had examined the affected parts of his leg the patient volunteered the information that the previous day his doctor had gone over his chest in the course of a general examination and listened to his heart. Pulling open his shirt, he showed me four perfect rings corresponding to the usual listening-sites. I asked whether the stethoscope was a metal one with a rubber-covered end, and the patient told me that that was so. I am informed that when the doctor listened to the heart no prolonged application of the stethoscope occurred, merely the usual fairly rapid auscultation, and yet the reaction provided four clearly marked red rings.

The above account demonstrates how easily slight contacts may be overlooked in cases of skin sensitivity.

Reviews

ENDOCRINOLOGY

Endocrinology: Clinical Application and Treatment. By August A. Werner, M.D., F.A.C.P. Second edition, thoroughly revised. (Pp. 924; illustrated 45s.) London: Henry Kimpton. 1942.

A Manual of Endocrine Therapy. By Bernard L. Cinberg, M.D. (Pp 178. New York: Brooklyn Chemical Publishing Company, Inc.; London. Macmillan and Co 1942.

There appears to be no end to the making of books on endocrinology, and it has therefore become our custom to draw attention to the special characteristic of each one rather than to discuss the details. Dr. Werner's *Endocrinology* throughout particularly emphasizes the close association between the endocrines and the autonomic nervous system, which is often insufficiently realized. Nevertheless we feel that the emphasis is not placed just where it should be in such statements as that the ductless glands act as governors over the autonomic nervous system, and that the present state of our knowledge of their functions is rendering such terms as neurasthenia, hypochondria, and nervous breakdown obsolete. Desirable as it is that such vague labels should be replaced by more accurate ones, we hesitate to believe that endocrinology will provide them. Surely of recent years the tendency has been the other way—to attribute to the hypothalamus a larger part in the control of the endocrines, while recognizing the psychosomatic origin of obscure nervous disorders. Once over that objection, the course becomes simpler, for we can approve unreservedly the prominence given by the author to the clinical aspect, while providing the reader with just that amount of anatomical, histological, and physiological information which will enable him to follow the argument without reference to other books. It is interesting to find Dr. Werner faithfully reporting cases successfully treated by preparations now often declared to be practically inert. As he states, when these products were used no better ones were available, and they are not recommended now. But it does show that here, as in other instances, the pharmacologist is a little too apt to sneer at purely clinical findings. The varieties of pituitary disorders are well described, and a judicial attitude is adopted on the vexed question of the number of individual anterior pituitary hormones. On the other hand the author has no hesitation in contradicting the ideas which have led to so lamentable a confusion between Simmonds's disease and anorexia nervosa. He is, however, more convinced of the existence of a male climacteric and of the hormonal origin of involutional melancholia than we should care to be. The lesser-known alimentary hormones are fully described, as is renin. Mongolism is regarded as an endocrine disturbance of pre-natal origin, but among the aetiological factors no reference is made to the age of the mother; it does seem clear, however, that this condition is particularly frequent if the mother is over 40 at the time of conception. The section on the thymus is judicial in tone, but the possible—even probable—association between hyperthymia and myasthenia gravis is not mentioned. Despite these minor points, here is a book of real usefulness.

Dr. B. L. Cinberg's *Manual of Endocrine Therapy* has a quite different purpose, which is to give a brief compendium of the subject without any attempt to provide a textbook. After the initial surprise at being informed that our knowledge (and not merely the therapeutics) of the endocrine system was very meagre until the discovery of insulin in 1922, we encounter a useful abstract of the therapeutic applications of each endocrine, briefly but critically stated, followed by a list of the preparations in current use, but omitting the polyglandular ones which are not biologically assayed. Only preparations thus standardized are recommended. There is also a useful chapter on diagnostic procedures, and a summary of therapy. A caution is given concerning the liability of desoxycorticosterone acetate to produce alarming oedema because of the rapid retention of sodium; this necessitates avoidance of large sodium dosage in conjunction with that synthetic hormone. It is curious to learn that the posterior pituitary has been used in the U.S.A. for the treatment of peptic ulcer, in view of the experimental work of Dodds and Noble, which showed gastric lesions could be induced by the injection of this hormone. The price seems high for so short a book.

MASSAGE, MANIPULATION, AND LOCAL ANAESTHESIA

Massage, Manipulation, and Local Anaesthesia By James Cyriax, M.D. (Pp. 302; 26 figures 12s. 6d.) London. Hamish Hamilton

This book is written primarily for "graduate masseuses and the practitioners from whom they receive instruction." A small amount of space is devoted to theoretical considerations, but the greater part of the work comprises practical instruction in dealing with the conditions that the physiotherapist is commonly called upon to treat. The book is wider in its scope than most written on this subject and the method of presentation and arrangement of material is good. The conditions in each part of the body commonly requiring diagnosis and treatment are dealt with, beginning at the head and neck and progressing in an orderly sequence to the ankle and foot. Following this are chapters on the use of local anaesthesia and on traumatic neurasthenia. Terms frequently appear which indicate the empirical nature of much of the treatment and a lack of precise knowledge of the cause of many chronic pains and aches; for example, "rheumatic inflammation" and "capsulitis." Some controversial subjects are dealt with in a dogmatic fashion, and certain definitions are a little hard to accept—for example, "Sciatica is synonymous with pain running down the lower limb from above whatever its origin." There is a good chapter on referred pain, and the importance is emphasized of the use of local anaesthesia in diagnosis and treatment.

The chapters that deserve special mention are those on the alimentary tract and on the use of local anaesthesia. In the former Dr. James Cyriax deals in considerable detail with indications for abdominal massage and the technique that should be used for the various conditions in which this treatment is of value. In the latter he first stresses the difference between diagnostic and therapeutic local anaesthesia; then gives the indications and contraindications for each, and the merits or otherwise of massage in relation to both types of injection. In the chapter on referred pain the diagnostic use of local anaesthesia is also emphasized.

The description of methods of examination of various parts of the body, particularly the back, is very good. Illustrations are not numerous and consist entirely of diagrams. There is a very apt paragraph dealing with the activities of the bonesetter. Those for whom this book is written will find it useful and stimulating.

A NOTEBOOK FOR JUVENILE COURT MAGISTRATES

A Notebook for the Children's Court By Margery Fry and Champion B. Russell. (Pp 24 1s post free.) Oxford: Howard League for Penal Reform. 1942.

The juvenile courts set up by the Children and Young Persons Act, 1933, are a vital part of the nation's defence against adolescent crime. To be effective they must be staffed by magistrates with special knowledge of children, their problems, and the ways in which they can be dealt with and assisted. Several valuable books have been written on this work, but these are mostly large and none too easy to read. This notebook is a slim, paper-covered volume into which two experts have put an amazing amount of legal and practical knowledge for the benefit of magistrates of children's courts. They sketch what they have found to be real requirements in the arrangement of the court accommodation, such as waiting-rooms and lavatories. They mention small and important matters like the lighting, which should not dazzle bench or witnesses or accused, and the seating arrangements, which should allow quiet conversation between magistrates, the clerk, the offender, his parents, and the probation officer. They give much useful advice on the way in which the bench should handle the cases, and carefully point out the many pitfalls of law and practice that await the unwary, such as the putting of incriminating questions to a child who is not giving evidence, the failure to warn a child of his right to go before a jury, or too ready an acceptance of a plea of guilty. Throughout this small volume the authors express a constructive and humane spirit; their instruction is all calculated to increase the confidence of accused children, their parents, and witnesses in the kindness and justice of the magistrates, and to help the magistrates themselves to make the best use of remand, probation, and t other means of disposing of delinquent children. These methc are summarized at the end of the pamphlet in a handy tab Of psychological examination they say that magistrates w make full use of the professional help that is already availat are not only doing wisely for the children but are helpi to build up a co-operation between science and law whi is full of hope for the future.

Notes on Books

A second impression has been published by Edward Arnold a Co. at 63s. of Sir H. Harold Scott's *History of Tropi Medicine*, based on his Fitzpatrick Lectures delivered before t Royal College of Physicians of London in 1937-8. These tv learned and comprehensive volumes were reviewed in a leadi article in the *Journal* of October 7, 1939. The second Gre Fire of London destroyed in its path some two million bool among them nearly 500 copies of this work. A reissue h therefore become necessary, and in an appendix the auth records certain quite recent advances of importance that ha taken place in the history of tropical medicine.

Dr. Hardie Neil has produced a third edition of a useful litt book on *Ear, Nose and Throat Nursing* (Auckland: Clark a Matheson, Ltd.). In the small compass of 126 pages the subje is covered as a whole but without that special reference nursing which the title suggests, though the after-treatment operations is described. The testing of hearing and t vestibular tests are not of much interest to nurses, whereas t feeding of patients, which is of great importance, might described with more detail and precision. There are al various descriptions of surgical technique, such as the autho method of ligaturing bleeding vessels in the tonsillar foss matters which do not concern nurses very much. The gener survey of the subject will be, and no doubt has been, usef to nurses, to whom the complicated illumination required practice renders the subject difficult and a little remote, b the emphasis on nursing is lacking.

Volume XLI of the *Transactions of the Ophthalmologic Society of the United Kingdom* for the session 1941 is publishe by J. and A. Churchill at 40s. The contents include Mr. Afflec Greeves's presidential address on macular oedema, and a repo of the discussion on ocular injuries resulting from the war. O of the sections was devoted to wartime ophthalmology, an Sir John Parsons read a paper on protection of the eyes fro war injuries.

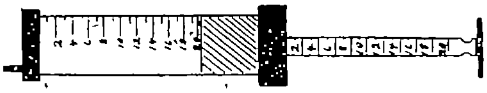
A copy of the *Collected Papers from the Middlesex Hospit* published during 1940-2 has been received from the canc and general research committee of the hospital, and can b consulted in the Library of the British Medical Association.

The National Institute of Economic and Social Research ha made arrangements for its publications to be issued by th Cambridge University Press. There will be two series "Economic and Social Studies," edited by Prof. A. L. Bowley and "Occasional Papers," the first of which is *The New Popu lation Statistics*, by R. R. Kuczynski.

Preparations and Appliances

SYRINGE FOR CONTINUOUS INTRAVENOUS ANAESTHESIA

Dr. S. C. Lewsen, M.R.C.P., writes: For successful co tinuous intravenous anaesthesia a fairly wide-bore needle intr duced deeply into the lumen of the cubital vein is desirabl Splints have been devised to hold the syringe, which shoul have an eccentric nozzle, in position. I have found a wid piece of elastoplast bound firmly to the syringe and round th arm very adequate and less cumbersome in the majority c cases. It is a simple matter to arrange the direction of th needle in the line of the vein by judiciously placed pieces o cotton-wool or lint between the arm and syringe. In orde however, to overcome the disadvantage of the elastoplast cove ing the graduation markings on the syringe, I have had a 2 c.cm. Record syringe made with a wide piston which has a fla surface graduated as shown in the sketch. This syringe wa made for me by the Medical and Industrial Equipment Co., Ltd



BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 10 1942

A TUBERCULOSIS POLICY

Soon after the outbreak of war in September, 1939, anxiety began to be felt lest history would repeat itself and there would occur a reversal of the favourable pre-war trend of mortality from tuberculosis. By the autumn of 1941 vital statistics had amply justified this fear, and on the analogy of the war of 1914-18 it seemed likely that the death rates from tuberculosis would continue to rise unless steps were taken to limit the spread of infection and to deal with the determining factors. At the request of the Ministry of Health the Medical Research Council appointed a Committee on Tuberculosis in Wartime. Its report has just been published, and on page 436 we print summaries of the findings and main recommendations as given in the report.

In 1939 and 1940 the increased tuberculosis mortality appeared to be mainly in young women. The committee's terms of reference were therefore : " To assist in promoting an investigation of the extent and causes of the wartime increase in the incidence of tuberculosis, particularly among young women, and also advise the Council regarding possible preventive measures." But a survey of the position up to the beginning of 1942 showed that all age groups had been involved to some extent in the increased tuberculosis mortality, and that those most affected included not only young women but also children and the older male age groups. The special experience of London in this respect is dealt with in the excellent article by Dr. Allen Daley and Mr. B. Benjamin at page 417 of this week's *Journal.* Furthermore, it was evident that a new programme of statistical, clinical, and pathological researches must take a long time to complete. In the committee's view the present situation and the evidence already in hand justified administrative action now. Its report therefore consists of a statistical analysis of existing data, a critical review of the available evidence, and practical recommendations based upon them. Great public interest has been aroused by the increase in tuberculosis, and we are therefore glad that technical terms have been avoided whenever possible, so that the reading and understanding of the report should offer no difficulty to the intelligent layman, while at the same time it will provide a clear account for the medical profession.

A short section on our present knowledge of the types and development of tuberculosis is followed by a full analysis of the general trend of tuberculosis deaths, 1939-41, and a comparison with the last war. The increase in tuberculous meningitis in England and Wales has so far affected all age groups up to 45. Children up to 10 years show a relative increase in mortality of 50%, but young adult males and females aged 15–24 also show a relatively large increase (50%), though the actual number of excess deaths in this age group is less than that for the children. In the discussion on the many factors that may be responsible in wartime for an increase in tuberculosis mortality it is pointed out that these may not apply in the same degree to all the age groups among which the increase had been observed. Where children are concerned due weight must be given to infection of milk, particularly because of the evacuation to districts where little or none of the milk supply is pasteurized. But attention must also be focused on contact infection in the home and that resulting from unsuitable billeting. In connexion with young adults, especially women, an age group particularly susceptible to environmental factors, nutrition and conditions of employment are stressed, and in particular the fatigue resulting from the relatively long hours they are now working. The increase in tuberculous meningitis, moreover, points to the introduction into industry of previously non-infected persons under conditions that tend to lower resistance.

The bulk of the report deals with measures for preventing further deterioration in the tuberculosis mortality ; and the members of the committee, while indicating full measures for the combating of tuberculosis in the light of our present knowledge, state that they have applied themselves in the first instance to what is practicable under existing conditions. This should make it clear that they regard none of their recommendations as hypothetical or " ideal " measures. Few will quarrel with the implied sentiment that universal and efficient pasteurization is long overdue, or with the suggestion that specially skilled workers in pasteurization depots should be placed on the list of reserved occupations and that workers in this category who have already been called up should be returned to their posts, and, lastly, with the further suggestion that when transport and other difficulties make it impossible for pasteurized milk to be delivered to the home the housewife should by suitable propaganda be instructed to boil it. To prevent the spread of infection from unsuspected cases of pulmonary tuberculosis and to improve the outlook of those suffering from the disease extension of mass radiography is strongly advocated. An excellent practical exposition of the subject is given, with its division into pre-employment, employment, and periodic mass radiography. While indirect (or miniature) radiography is the method of choice in wartime (the essentials of this form of apparatus and the principles to be applied in its use are given in an appendix), the committee rightly stresses that the miniature method should be undertaken in preference to direct radiography, not merely for reasons of cost but rather where reasons of speed *plus* cost demand it, and recommends that, until apparatus for miniature radiography becomes available, mass radiography schemes should be instituted by means of the ordinary direct method. Indeed there are likely to be many instances in which full-size direct radiography will be at least as suitable a basis for a mass radiography scheme as the miniature method. It is recommended that for the present " miniature " apparatus already available or shortly to become available should be under the general direction of the Ministry of Health in order that the best possible use of the limited apparatus is ensured.

The care of persons discovered by mass radiography to have tuberculous lesions is discussed, and it is emphasized that the success of both mass radiography schemes and the treatment of those found to be suffering from active disease are intimately bound up with the removal of certain essential difficulties in the way. The first is shortage of institutional accommodation. Next, cogent reasons are adduced for improving the present financial provision for tuberculous patients. Thirdly, full consideration is given to industrial rehabilitation of both the convalescent non-infective and the chronic active case. Several possibilities in Great Britain are mentioned, involving part-time (ordinary work but with the number of hours reduced) and modified work (work, either full-time or part-time, carried out under less strenuous conditions than usual), with supplement to wages in each case. Insufficient emphasis is perhaps laid on the setting up of industries in connexion with sanatoria for both residents and non-residents, a solution for rehabilitation of the tuberculous strongly favoured by some authorities; but probably it is a method practicable only to a limited extent in wartime. We would point out here that the subject of rehabilitation and care of the tuberculous has also been dealt with by a special committee of the Joint Tuberculosis Council.[1]

A further section of the report is concerned with measures that should be taken to raise the resistance of the population to the tubercle bacillus, particularly in susceptible groups, and tribute is paid to measures already taken by the Government to maintain in general the national health under war conditions. But more is indicated, and stress is laid on nutrition, favourable working conditions, fatigue, and domestic overcrowding. Continued emphasis is to be laid on the examination of contacts, particularly of children under 5 and young adults (15–30), and such examination should always include an *x*-ray examination, and tuberculin testing in the case of children. It is recommended that billeting authorities should be made aware of homes that are unsuitable for billeting on account of tuberculosis, and that they should be notified of any case of tuberculosis among those to be billeted. There is one notable omission. An important feature of the antituberculosis campaign should be the special care of pregnant women suffering from or suspected of tuberculosis. A valuable recommendation would therefore have been that a radiograph or screening of the chest should form an essential part of the antenatal examination of every pregnant woman, to be followed by a repetition of such an examination within two months of labour. And we would also emphasize, more than is done in the report, the need for reorganization of the tuberculosis services, whose efficiency varies very widely in different parts of the country. Even in wartime certain improvements may be possible, and at all events, as is pointed out in the report, steps should now be taken to study the best methods by which reorganization could be accomplished when circumstances permit.

The committee rightly points out that if its recommendations are implemented this should be accompanied by information and propaganda both to the medical profession and to the public. No one connected with tuberculosis work, however remotely, or for that matter with public health in general, should miss studying this report. We hope that there will be no delay in bringing forward legislation which will give effect to the important recommendations contained in it.

ANATOMY OF THE BRONCHIAL TREE

The description of the bronchial tree in the standard textbooks of anatomy is at present incomplete and largely inaccurate. To most students the lobar bronchus is in uncharted country as soon as it has entered the lung substance, and its distribution is described only vaguely by the statement that it divides into alternate ventral and dorsal branches. In spite of the studies of Aeby (1882) and Ewart (1889), and of certain later authors (Nelson,[2] 1934; Kramer and Glass,[3] 1932; Neil,[4] 1939), a more exact knowledge of the segmental distribution of the bronchi within the lobes has been limited to but a few workers, chiefly those engaged in the special study of diseases of the lungs. The remarkable development of thoracic surgery during the last decade has introduced more and more people to this general inadequacy in understanding of the anatomy of the bronchial tree, and it is no exaggeration to say that the need has become almost urgent for a complete revision both of the details taught to students and of the conception held by most practising doctors; and in this are included pathologists and radiologists as well as clinicians.

It should be imperative to the physician or surgeon who is specializing in diseases of the chest to acquire this complete knowledge, for without it an understanding of many fundamental aspects of intrapulmonary disease is necessarily incomplete. Thus, the important condition of lung abscess and its associated grades of septic pneumonitis is inseparably linked with this segmental anatomy, whether it be from the causal aspect, radiological interpretation, medical treatment, or surgical approach. The day when radiologist, physician, and surgeon were all content with a single postero-anterior radiograph of the chest and a conclusion that the lesion was situated in the upper, middle, or lower "zone" is now, we hope, long past. The first essential, therefore, for a proper study of many lung lesions is a basic knowledge of the anatomy of the bronchial tree, obtained from careful study of good casts and preparations, preferably augmented by personal dissection. The study of an actual case demands a lateral radiograph of the chest in addition to a postero-anterior, usually good bronchograms, and often bronchoscopic examination as well. It is surely as illogical to be content with an imperfect knowledge of the anatomy of the bronchi as to expect a surgeon to do his work efficiently elsewhere in the body without that exact anatomical background which is accepted as essential in his training. Students in both the pre-clinical and clinical subjects should be taught this anatomy, and appropriate questions should be asked in examinations.

Among recent papers on bronchial anatomy is one by Foster-Carter[5] (1942), which gives a brief and lucid account of the most modern studies of the problem, supported by a consideration of the comparative anatomy and development of the bronchial tree, by diagrams, actual illustration of certain specimens, by bronchograms, and by a celloidin cast. Those wishing to improve or refresh their knowledge of the bronchial distribution will find much of value in this paper. Certain previously confused areas, such as that of the distribution of the upper lobe bronchi, are described with more accuracy and clarity than in most earlier publications. In spite of the excellence of this account, it is desirable to draw attention to certain defects, more especially since they closely follow ones that appear in almost all previous papers. The first of these is the nomenclature. A certain confusion already exists in terminology, and many of Foster-Carter's own suggested names do not make for further clarity, as, for instance, his insistence on retention of the term "eparterial bronchus" for the branch to the right upper lobe and his introduction of the term "hyparterial bronchus" for the bronchus to the left upper lobe. A new name is worthy of acceptance if it either corrects a previous inaccuracy or is more clearly descriptive than the old one it seeks to supplant. It is difficult to see that the name "hyparterial bronchus" could by any possibility suggest accurately that it refers to the left upper lobe bronchus. Finally, there is the misuse of diagrams and drawings. A diagram or drawing, even in these days of excellent photography, may be desirable in order to express clearly and easily what perhaps can be shown only imperfectly by even the most skilful photograph. For the demonstration or teaching of anatomical features that have been worked out beyond all possible doubt they may be excellent; for the portrayal of features that have not been so widely investigated and

checked they are dangerous when unsupported by exact evidence; the author's own impressions or bias tend to creep in, and errors appearing in other apparently authoritative papers tend to be perpetuated. In almost all the papers on bronchial anatomy published during the last ten years this error is most apparent. Faulty diagrams abound. Although the diagrams in Foster-Carter's paper are much more accurate, certain misconceptions have again been perpetuated. The arrangement of the segments of the lingular process of the left upper lobe is, for instance, incorrectly portrayed, and the description of the lower lobe segments is lacking in that accuracy and completeness that is necessary if it is to be accepted as final.

A NEW METHOD OF AIR DISINFECTION

From recent work in England on the chemical disinfection of air two principal methods have emerged, both of which are certainly efficient, although neither has yet been applied in circumstances and on a scale which would prove its capacity to prevent the spread of air-borne infection. One of these is the spraying of hypochlorite solutions, which are believed to owe their effect to the liberation of hypochlorous acid gas. The other is the production of an "aerosol" or mist of very minute fluid particles consisting of or containing a germicide; these minute droplets are not intended to evaporate, and are believed to act by collision with bacteria-laden particles. Both because some of the germicides are poorly soluble in water, and because watery solutions evaporate, whereas a good aerosol should be persistent, propylene glycol has been used as a solvent: C. C. Twort and his colleagues,[1] for example, found the best of many reagents they tested to be a solution of hexyl resorcinol in propylene glycol. It was briefly announced last year by American workers who had taken up this study that propylene and other glycols are themselves air disinfectants of remarkable efficiency. A fuller account of this work has now been published by O. H. Robertson and his colleagues.[2] Their methods were of a nature now recognized as appropriate for this form of study, employing test and control chambers with adequate air circulation and the means of spraying in bacterial suspension and the germicide, and a device for obtaining plate cultures from measured samples of the contained air. Their chief observation is, briefly, that spraying such an amount of propylene glycol as to give a concentration of 1 g. in 2,000,000 c.cm. of air kills any of numerous species of bacteria almost instantly, even though their concentration be as high as 500,000 per litre of air. There were a few survivors for some minutes when the concentration of propylene glycol was 1 in 7,700,000; but even 1 in 50,000,000 had a pronounced bactericidal effect. By various forms of experiment, including mouse inoculation with washings of air sprayed with virulent pneumococci, it was shown that there is a true killing effect, sterile cultures from the air treated with propylene glycol not being produced in any of several other theoretically possible ways. Ethylene and trimethylene glycol were equally effective; glycerin had little action.

Droplets of propylene glycol evaporate rapidly, and as similar bactericidal effects are produced by pre-formed vapour it is concluded for this and other reasons that propylene glycol acts bactericidally as a vapour, and not in aerosol form. The contrast between its behaviour in air and in water is extreme: pneumococci will grow in broth containing 5% of it, and staphylococci in 10%. On the other hand suspension in 80% to 90% propylene glycol is immediately lethal to both. This is evidently bactericidal action of a quite unfamiliar kind, and no light has yet been obtained on its mechanism. Apart from its astonishing behaviour as a vapour, the peculiar effect of concentration on the behaviour of propylene glycol, in liquid form should repay further study. The authors have tried Twort's hexyl resorcinol solution, and found it somewhat more effective than propylene glycol alone. Atmospheres containing the vapour of pure propylene glycol, on the other hand, are odourless and non-irritating and, so far as is known, non-toxic; administration of the liquid is without toxic effects. On present evidence, this method of disinfecting air seems even more promising than those with which work in England during the past few years has made us familiar.

ACTION OF DRUGS ON THE COLON

The drugs in common use for the treatment of post-operative distension and paralytic ileus belong to two groups—the parasympathomimetic and posterior pituitary. The theoretical basis for employing the former group is well established, and its action is explained either by the replacement of the natural neuromuscular transmitter by synthetic choline derivatives, or its enhancement by physostigmine or prostigmine, owing to the inhibition of cholinesterase. In practice it has been found that although carbamylcholine and acetyl-β-methylcholine are effective stimulants of the gastro-intestinal tract, since they are not so rapidly destroyed as the natural acetylcholine, yet for that very reason they cause in effective doses unwanted side-reactions such as flushing, sweating, increased salivation and lacrimation, and a fall in blood pressure.[1] Physostigmine, though equally effective in stimulating the colon, is open to the same criticism; but prostigmine, the synthetic substitute introduced in 1931, is singularly free from these objections and has been used with success in the prophylaxis and treatment of post-operative distension and paralytic ileus.[2] [3] The action of the posterior hormone on the large intestine has been strongly disputed, chiefly on the basis of experiments in dogs, which are not necessarily applicable to man. The vasopressor fraction can be used in the treatment of these conditions, though it is contraindicated in the presence of cardiovascular disease because of the coronary vasoconstriction. It has been argued that to be effective a drug should increase the propulsive activity of the large intestine rather than its segmenting movements. It is not true that any substance which is at all active will stimulate both equally, for morphine depresses peristalsis in the colon while increasing the tone.[4] On this basis physostigmine and prostigmine, which are believed to work by the enhancement of the natural processes (and an enema is an invaluable accessory), will be the drugs of choice.

Adler, Atkinson, and Ivy[5] have studied the action of various combinations of drugs upon 4 trained dogs with appendicostomies and 4 "fit" adults with colostomies. They used a modified balloon technique by which the propulsive force of peristalsis could be directly measured. In man, pituitrin, physostigmine, and prostigmine all increased the "propulsive motility" of the colon, but it was not possible to grade the dosage of physostigmine so as to avoid side-reactions. Oral administration of prostigmine (15 mg.) was effective after several hours' delay.

[2] *Lancet*, 1934, **1**, 942

[3] *J. Amer. med. Ass.*, 1938, **110**, 1165.

[4] *Physiol. Rev.*, 1937, **17**, 618.

[5] *Surg. Gynec. Obstet.*, 1942, **74**, 809.

Ergotamine given by itself had no discernible effect, but greatly increased and prolonged the action of the other drugs; and the authors concluded that a combination of ergotamine tartrate (0.25 mg.), prostigmine methylsulphate (0.25 mg.), and pituitrin (1.25 units) was the most effective, and worth trial in the treatment of post-operative distension and paralytic ileus. There is as yet no entirely satisfactory explanation of the synergistic action of ergotamine, though it is known that relatively bigger doses may stimulate the large intestine in intact animals. But this property may be used to increase the activity of the other drugs on the colon and so diminish their unwanted side-effects.

MALENESS, FEMALENESS, AND MENTAL DISEASE

It was noted a good many years ago by Mott in this country and by Myerson in the United States that male relatives of men suffering from mental disease are more frequently affected than are female relatives, and that this tendency is reversed in the case of women patients. It is difficult to devise any plausible explanation for this distinctly peculiar form of familial sex limitation. Penrose[1] has produced an ingenious hypothesis which, though highly speculative, does suggest a reasonable basis for the phenomenon. In addition it links together a number of diverse facts and also has the great merit of indicating useful lines of study for the future. From the psychological point of view maleness and femaleness are not two sharply contrasted characteristics. To some extent everyone is psychologically bisexual; but in normal persons there is a preponderance of instincts concordant with physical sex. It is possible to devise interest ratings, etc., which show a continuous gradation from the strongly female to the strongly male. Males and females occur in whom deviations in the normal direction are less marked, and finally there is some overlapping, a proportion of persons possessing frankly some of the instincts normally displayed by the other sex. There is in fact a continuous distribution which is clearly bimodal, but which equally clearly shows some overlap. It has also been found by observation and experiment with other forms that the underlying mechanism of sex determination is quantitative and not qualitative. A number of genes make for femaleness, a number for maleness; the result depends upon the balance. The selective advantage of clear-cut physiological division is such, however, that the mechanism has become so arranged that one or other balance is nearly always attained, and physical intersexes are therefore rare.

In man sex determination depends upon the X-Y chromosome mechanism. An individual with two X's is a female; one with an X and one Y is a male. But the discovery by Haldane of partially sex-linked characters in man, showing that sex determination is probably not the sole function of the X-Y pair, has as a corollary the possibility that autosomes (chromosomes other than sex chromosomes) play some part in sex determination. Sex determination may be brought about by some such mechanism as the following, though rather more elaborate. There reside on the X chromosome a concentration of genes making for femaleness, which are balanced by genes making for maleness situated in the other chromosome pairs. Two sets of the female-producing X genes overcome the complete set of male-producing genes, whereas one set alone is overcome by them. Human mental development being so recent, it may well be that mental sex constitution is inherited in a more primitive way than physical sex and is less concerned with the sex-chromosome balance. Imagine a gene, situated upon an autosome, which increases the quality of femaleness. Such a gene passed on by a man would tend to swing his sons in the direction of femaleness and in his daughters would, so to say, confirm their femininity. In short, such genes, though they would be transmitted by males or females, could only affect members of like sex in a family in the same sense; the same type of abnormality would tend to be present in father and son or in mother and daughter.

An association between sex inversion and mental disease has often been claimed, and so, Penrose argues, a hereditary mechanism of this kind determining psychological sex traits should be reflected in just that way observed by Mott and Myerson. Penrose shows that their figures when added together do indicate a highly significant tendency for affected relatives of lunatics to be of like sex. He produces further figures of his own, analysed in greater detail and based on the family records of 1,000 mental patients. The correspondence in this series also is highly significant. Penrose puts forward one or two alternative explanations, but regards the hypothesis outlined above as simpler and more comprehensive.

LATERALITY DOMINANCE IN SHAKESPEARE

Considered in all its implications there is no more fascinating neurological topic than handedness. The distinction between the right- and left-handed is probably as old as mankind; and the contrast between symmetry of structure and asymmetry of function must have puzzled men from the first. It was natural for primitive man to attribute a symbolic meaning to natural occurrences, and here was a distinction inherent in his nature and ready, as it were, to his hand. To the Roman augur the bird on the left was sinister indeed. Drs. G. Walsh and R. M. Pool[1] have sought for references to right- and left-handedness, or laterality dominance as they call it, in Shakespeare's plays, and found that "he is as positive as were the ancient Hebrews in the glorification of the dexter side of the body and the condemnation of the sinistral. . . . Around the left hand and the left side of the body the dramatist encounters an aura of evil." There are not many references to handedness in Shakespeare, and in some the use of right and left is no more than conventional. The most convincing evidence for a characteristically Shakespearean twist to the distinction is to be found in the instance in which disfigurement is placed upon the left side: the mole on Imogen's left breast and the wart on Dromio's left arm are examples. Hand-to-hand fighting in a predominantly right-handed world would lead to scars on the left side of the body, a fact which is reflected in several quotations. The authors do not mention a reference to laterality which occurs in *King John*—"Slippers, which his nimble haste had falsely thrust upon contrary feet." This drew from Dr. Johnson the surprising comment, "Shakespeare seems to have confounded a man's shoes with his gloves. He that is frighted or hurried may put his hand into the wrong glove, but either shoe will equally admit either foot." Sir Walter Raleigh infers from this that Johnson "wore his boots indifferently, either on either foot, and further, which is yet a stranger thing, believed that all other boot-wearers practise the same impartiality." He adds, "This is a topic which demands, and would well repay, the expert labours of academic research. Very little is known about Johnson's boots." Perhaps this enchanting subject will tempt Drs. Walsh and Pool to a new study of literary laterality.

Sir Wilson Jameson will deliver the Harveian Oration before the Royal College of Physicians of London on Monday, October 19, at 2.30 p.m., at the College.

LOUSE-BORNE TYPHUS FEVER

BY

Sir J. W. D. MEGAW, M.B., D.Sc., I.M.S.(ret.)

(*Concluded from p.* 403)

Diagnosis

The diagnosis of severe cases in established epidemics is easy and mistakes are rarely made. On the other hand sporadic cases, especially when they are mild, are often missed. An attitude of watchful suspicion and resort to laboratory tests are essential if these mistakes are to be avoided. M. D. Mackenzie states that 87 groups of cases have occurred in Glasgow between 1901 and 1926: in 36 of these the first case was wrongly diagnosed. There is reason to suspect that a good many sporadic cases may have occurred in this country without being detected. In every case in which there is the slightest possibility that the disease may be typhus early and repeated Weil-Felix tests should be carried out. This test, though not infallible, is by far the most reliable method of diagnosis that is generally available. All large laboratories have facilities for carrying out the reaction, which in most cases becomes positive before the end of the first week, though it may, exceptionally, be delayed till the ninth or tenth day, and in rare cases it remains negative. The special feature of the reaction is that the titre of agglutination rises rapidly, usually reaching heights of 1/500 or over towards the end of the fever or in early convalescence; then it falls to a low level, but titres of 1/50 or 1/100 may persist for weeks or even months. A reliable strain of *Proteus* OX 19 is essential; this is best obtained from the Oxford Standards Laboratory. In Great Britain complete naked-eye agglutination in a dilution of 1/100 is strong evidence of typhus fever, but if repeated tests are made the maximum titre is seldom less than 1/500. If the titre remains constant throughout the illness and convalescence a false positive should be suspected even if the reaction is positive in dilutions of 1/200 or more. The reaction is also positive in rising and falling titre in flea-borne typhus, often also in tick-borne typhus, but so rarely in other diseases that mistakes are very unlikely to occur. Recent work in America suggests that agglutination tests in which suspensions of *R. prowazeki* made from yolk-sac cultures are used may prove to be more strictly specific than the Weil-Felix reaction. The same remark applies to complement-fixation tests in which similar cultures are employed as the antigen; but neither of these tests has yet come into general use.

When laboratory facilities are available an attempt should be made to isolate the virus by intraperitoneal inoculation into guinea-pigs of 2 to 5 c.cm. of blood taken from the patient at the height of the fever. Isolation of the virus is the one method by which an absolute diagnosis can be made.

When persons, who have been inoculated against fevers of the typhoid group are attacked by typhus the Widal reaction is often positive in rising and falling titre, so that a mistaken diagnosis of typhoid has often been made by medical men who were not aware of this fallacy in the reaction. When inoculated persons are suspected of having typhoid and the blood cultures are negative the serum should be tested for typhus by the Weil-Felix reaction. The Wassermann reaction also may be positive during attacks of typhus.

For rapid bedside diagnosis a modification of the Weil-Felix reaction is sometimes used. A drop of the patient's serum is placed on a glass slide; to this is added a drop of suspension of *Proteus* OX 19 which has been tinted with methylene blue; the mixture is then tilted up and down for two or three minutes. In positive cases clumping is visible to the naked eye, but the standard test should be carried out in all reactors to find the titre of agglutination. Another modification has quite recently been described by German workers; this, called the "dry-blood agglutination test," has already proved its value as a means of making large-scale surveys of suspected populations. One or more droplets of each person's blood are allowed to dry on a labelled glass slide; suspensions of *Proteus* OX 19 are afterwards stirred in over the dried droplets; the slides are tilted up and down, and the results observed at intervals up to 10 minutes. In positive cases the clumping can easily be seen with a pocket lens. The standard test should be carried out in all positive cases.

Differential Diagnosis.—Typhus fever may simulate typhoid, meningitis, influenza, bronchitis, pneumonia, febrile catarrh, appendicitis, measles, small-pox, dengue and other fevers, especially during the first few days before appearance of the rash and development of agglutinins. Differentiation is seldom difficult if typhus is suspected and the usual laboratory tests are made. The simultaneous occurrence of other diseases, even in the same patient, is not infrequent during epidemics; in such cases serious mistakes may be made if a complete examination is not carried out. Flea-borne typhus can be distinguished from louse-borne typhus only by animal inoculation, though a knowledge of the conditions in which the infection has occurred will usually prevent difficulties from arising.

War Typhus

Typhus fever is far more common and far more deadly in the conditions resulting from war than in times of peace. Great movements of population often involve the transfer of susceptible persons to infected areas or of infected persons to places previously free from the disease. In either case the virus finds a virgin soil in which it flourishes. Overcrowding and lack of facilities for washing cause a great increase in the louse population and in the opportunities for migration of the insects from one host to another. Malnutrition causes lowering of resistance to infection. These factors lead to an acceleration in the rate of transmission from man to man and so to an increase in the virulence of the infection. Correspondingly, the incubation stage is shortened to an almost uniform period of about 8 days; mild attacks are less common and the death rate is higher. Even in areas in which the disease is smouldering in mild endemic form the risk to troops is great, because the soldiers are usually new-comers from non-infected places and so are highly susceptible.

Prevention

The best method of prevention is to eliminate louse infestation. This is a simple matter in normal conditions, but in war it may be very difficult or even impossible. The military medical authorities are fully alive to the importance of the problem; they have worked out an organization to deal with any conditions that can be foreseen. But no regulations, however perfect, can relieve the medical officers of the responsibility for constant vigilance; they must suspect typhus in every doubtful case of fever in areas of possible endemicity, and they must keep a careful watch on the health of the local inhabitants as well as of their own personnel. If the troops are stationed for any length of time in a suspected locality useful information can often be obtained from the local medical men; but undue reliance must not be placed on negative reports; because infection often smoulders in areas which appear to be free from the disease. The "dry-blood agglutination test" already mentioned deserves consideration as a rapid method of carrying out a survey in suspected localities: it has been used with success in German-occupied countries. The test can be carried out more rapidly and easily than the search for malaria parasites in blood films. Details of the method are given in the *Bulletin of War Medicine*, May, 1942, p. 397, and the *Tropical Diseases Bulletin*, June, 1942, p. 372.

The personnel engaged in typhus work of every kind should be young because of the great risk to life in the case of elderly persons. Preliminary inoculation should also be carried out if possible. In dealing with infected persons disinfection of the patient's skin by chemical antiseptics is desirable because of the risk of infection from louse faeces. Buxton suggests lathering the skin with a mixture of 1½ oz. of Jeyes' fluid, 1½ lb. of soft soap, and 10 gallons of water as a preliminary to bathing. For the same reason clothing and bedding should be disinfected by heat rather than disinfested with cyanide gas, which is of special value in the disinfestation of rooms and furniture. Special louse-proof clothing should be worn by persons exposed to risk: if this is not available a fair degree of protection is afforded by wearing rubber gloves and gum-boots into which the sleeves and trousers are tucked; the arms and legs should be smeared with camphorated oil made of 1 part of camphor to 9 parts of olive oil or liquid paraffin. The clothing must be changed frequently, and on each occasion a hot bath should be taken after preliminary lathering of the skin with a medicated soap of the type suggested by Buxton.

Medical men in Great Britain will find useful information about preventive measures in the Ministry of Health Memo. No. 252/Med. The general practitioner must always play a leading part in the detection of the first cases: he and the staff of our hospitals ought to keep a close look-out for suspicious cases. There is no need for an alarmist view of the risk of infection in this country; conditions here are very different from those prevailing in great epidemics, in which the danger to the medical and nursing personnel is very considerable. On the other hand the attitude of the medical profession should be one of uncompromising hostility to louse infestation, which is still far too widespread here. Educational propaganda directed towards arousing feelings of disgust and fear against lice must be combined with measures for the control of the insects.

Preventive Inoculation

Many kinds of protective vaccines have been tried; these fall into two main groups: (1) killed vaccines made from the rickettsiae of the disease; and (2) living vaccines containing the rickettsiae of flea-borne typhus, which have antigenic properties similar to those of louse-borne typhus. The living virus, attenuated in various ways, has been used on a large scale in French North Africa with apparent success: the vaccine acts by causing an unapparent or mild attack of the disease; but in some cases severe or even fatal attacks have resulted owing to an unexplained increase in virulence of the rickettsiae. There is a natural reluctance to use a virus whose constancy cannot be guaranteed, and, besides, there is some risk of introducing infection into places which are free from the disease.

Killed vaccines are free from risk; the first of these to be used on a large scale was Weigl's vaccine, which undoubtedly gives a considerable degree of protection. The preparation of each course of vaccine for one person involves inoculation per rectum of about a hundred lice, which have to be fed for some days on immunized persons and then dissected to extract their infected guts. This vaccine is clearly impracticable for everyday use. Cox has worked out a method which holds out promise of success; he grows cultures of *Rickettsia prowazeki* in the yolk sacs of developing chick embryos; suspensions of these cultures contain enormous numbers of rickettsiae, and large quantities of killed vaccine can be prepared at a small cost. The vaccine immunizes animals, but the crucial test of its effectiveness on human beings has not yet been completed. German workers have naturally been interested in Cox's vaccine; they are known to have taken up its preparation, and there are suggestions that it has already been found effective in reducing the severity of attacks which have occurred in inoculated persons. Killed rickettsial vaccines have not hitherto been found capable of producing complete immunity against virulent infection, but there is good evidence that they often lessen the risk to life.

The control of typhus fever in war conditions may be extremely difficult, as is shown by a report which appeared recently in a German medical journal. No fewer than 117 men engaged in guarding prisoner-of-war camps in one military district in Poland were attacked in November and December, 1941, in spite of delousing and orders to avoid close contact with the prisoners. The fatality rate was 35% in 82 of these persons who had not been vaccinated, but was *nil* in 35 who had been given one or more doses of a vaccine of unspecified type. In the same report there is a statement that 104 cases of a milder form of the disease were treated in the same hospital in the following two months. The patients were soldiers who had just returned from the eastern front; they had evidently become infected on the journey, but the virulence of the infection was low and there were no deaths.

Treatment

German physicians have been trying hard to find a curative drug, but although some of them have made great claims for sulphapyridine others are equally emphatic that it is useless except, possibly, in complications caused by organisms for which it has a specific action. The latest claim is for mepacrine hydrochloride (atebrin), preferably combined with pamaquin (plasmoquine); detailed evidence is promised, but in view of past disappointments it may be best to avoid undue optimism. No further reports have appeared about the use of intravenous solutions of chlorine which were claimed by Danielopolu to give almost miraculous results in the severest cases. Convalescent serum or direct transfusions of blood from convalescents may have some value if given early, but few observers are enthusiastic about their efficacy.

Good nursing and a light nutritious diet, rich in all the vitamins, form the basis of treatment. The free use of subcutaneous injections of normal saline or Ringer's solution is advocated by several physicians. Plenty of liquid should be given by the mouth. Chloral hydrate in doses of 15 to 40 gr. often relieves headache, joint pains, insomnia, and restlessness: if it fails lumbar puncture may be needed. Warm or even hot baths have their advocates. Complete rest, attention to the toilet of the mouth, and the prevention of bed-sores are other important points. Even in mild cases the patient must be kept in bed for at least a week after the temperature has fallen: in severe cases complete rest for periods up to three weeks or longer is essential because of the risk of sudden heart failure. For anaemia, iron and liver extract are needed.

In a disease which shows such extreme variations in the severity of different outbreaks, and even at different periods during the same outbreak, great caution is needed in estimating the effect of any special line of treatment. With any scheme of treatment the case mortality may range from *nil* to 30% or more.

The Other Fevers of the Typhus Group

As already stated, these are primarily diseases of lower animals, or "zootic" diseases, and are not capable of being naturally transmitted from man to man as is the case with louse-borne typhus, which is primarily a human, or "demic," disease. This general statement needs qualification in the case of flea-borne typhus: this disease is caused by a virus which is so closely related to *R. prowazeki* that many experts regard it as a variety of that organism rather than a distinct species. Some workers hold that the virus of flea-borne typhus, after being transmitted in the first instance from rat to man by the rat flea, may at times become capable of being transmitted from man to man by human lice. This is a disputed point, but even if the virus should occasionally be transmitted from man to man the resultant disease would automatically become louse-borne typhus and would have to be handled accordingly. Flea-borne typhus may possibly be the ancestor of the human disease, whose virus in that case would have originated as a modification of the rickettsiae of flea-borne typhus.

The other "animal" typhus fevers which are conveyed to man by ticks and mites, respectively, have never been known to be transmitted in natural conditions from man to man; cases of these diseases do not call for special precautions to prevent the spread of infection to contacts. On the other hand the possibility that flea-borne typhus may be transmissible by lice must be borne in mind; cases in louse-infested persons or communities should be handled on the same lines as louse-borne typhus, even though the risk of infection is doubtful or negligible in most of the affected localities.

Flea-borne Typhus

This is primarily a disease of rats, perhaps also of mice; it is ordinarily conveyed to man by the rat flea. The usual names of the disease are "murine typhus" and "endemic typhus," but neither name is appropriate: mite-borne typhus is also a murine disease, and both tick-borne and mite-borne typhus have an equal right to be called endemic diseases; even louse-borne typhus often occurs in endemic form. The numerous other names that have been given to the disease are equally unsuitable. Flea-borne typhus was first recognized only a few years ago, but already it is known to be widely distributed in many parts of the world; the only condition essential for its occurrence is contact between human beings and infected rats which harbour fleas. This contact is most frequent in houses in urban areas, so that the disease is chiefly urban or, at any rate, domestic in type, as opposed to tick-borne and mite-borne typhus fevers, which are rural in their distribution.

The virus, called *Rickettsia mooseri*, is similar in its serological and immunological features to that of louse-borne typhus, but it causes a milder disease in man and a more serious disease in rats than *R. prowazeki*. Mention has already been made of the possibility that the virus may in exceptional conditions become modified so as to be transmissible by human lice from man to man. Some French observers believe that the virus can be conveyed by food which has been contaminated with the faeces or urine of infected rats.

The clinical features of flea-borne typhus are very similar to those of mild louse-borne typhus; the case-mortality rate is very low as a rule, but virulent forms of the disease have been reported from Mexico and elsewhere. The disease should be suspected, even in this country, when sporadic cases of typhus-like fever occur in persons who are free from louse infestation and who have not been in contact with cases of louse-borne typhus. In countries where tick-borne or mite-borne typhus occurs there is often a difficulty in differential diagnosis, but knowledge of the epidemiological conditions, and laboratory tests if available, will usually be of great help. The rising and falling titre of agglutination to *Proteus* OX 19 is the same as in louse-borne typhus, and the reaction to *Proteus* OXK is negative or weak. Prevention is by rat destruction on the same lines as in plague.

Tick-borne Typhus

This disease occurs in many areas in North and South America, Asia, North and South Africa, and Southern Europe. Cases occur chiefly in temperate and subtropical climates during the season of activity of the vector ticks. The chief risk of infection is from bites by ticks which have been infected by animals in the open country or forests of affected areas, so that the disease is rare in urban communities. The handling of ticks which infest dogs has been regarded as the source of infection in some cases. Certain areas in the Rocky Mountains are the home of the classical form of the disease. The virulence of the infection is extremely variable; in some localities it is so great that the case-mortality rate is 70%; in others it is only 5%.

The onset and decline of the fever are usually more gradual than in louse-borne typhus; the rash is maculo-papular and usually extends to the palms, soles, and face. In some localities a local sore with lymphangitis often occurs at the site of the tick-bite. The agglutination response to *Proteus* OX 19 and OXK is very variable, ranging in each case from negative to strongly positive. Complement-fixation tests or agglutination tests in which the specific rickettsiae are employed may prove to be reliable methods of differential diagnosis from the other typhus fevers.

Prevention is by frequent examination of the body for ticks or by wearing tick-proof clothing when living or travelling in affected localities. If the ticks are removed within an hour or two after attaching themselves there is little risk of infection. A drop of tincture of iodine or kerosene should be applied to each tick before it is removed. Killed vaccines made from suspensions of laboratory-infected ticks have been used with success, and now yolk-sac cultures of the rickettsiae are being tried.

Mite-borne Typhus

This disease occurs chiefly in the Far East; cases have also been reported from India. The disease is rural in distribution; the causal rickettsiae are conveyed from infected rats by larval mites, which are microscopic in size. Japan is the home of the historical form of the disease; in that country a sore with lymphangitis is said to be uniformly present at the site of the infecting bite, but in other affected countries this is often absent.

A strongly positive agglutination reaction to *Proteus* OXK with a negative or weak reaction to *Proteus* OX 19 is highly suggestive of mite typhus: in other respects the disease has a general resemblance to tick typhus. The virulence of the infection shows the same variability according to locality as is seen in tick typhus.

References.—The recent contributions to knowledge of the typhus fevers are so numerous that detailed references to the literature cannot be given in the space available. Abstracts of the important articles appear in the *Tropical Diseases Bulletin* at frequent intervals

Fevers of the Typhus Group

	Epidemic Typhus Fever (preferably called "Demic" Typhus Fever). A human disease, transmitted from man to man by human lice. Associated with louse infestation, poverty, famine, and overcrowding.	The Non-epidemic Typhus Fevers (preferably called "Zootic" Typhus Fevers). Primarily diseases of lower animals, transmitted secondarily to man by fleas, ticks, or mites. Associated with life in the open country and forests or with contact with rats, dogs, etc. "Place" diseases and usually sporadic.		
Names	Louse typhus	Flea typhus	Tick typhus	Mite typhus
Synonyms	Typhus fever, typhus exanthematicus, etc.	Murine typhus, endemic typhus, shop or urban tropical typhus	Rocky Mountain spotted fever, boutonneuse fever, tick-bite fever, etc.	Japanese river fever, tsutsugamushi, scrub tropical typhus, etc.
Virus	*Rickettsia prowazeki*	*Rickettsia mooseri*	*Rickettsia rickettsi*	*Rickettsia tsutsugamushi*
Vectors	Human lice	Rat fleas	Various ticks	Larval mites
Reservoirs of infection ..	Man only known	Rats and mice	Various rodents; dogs and other animals suspected	Rats
Agglutination against:				
Proteus OX 19 . ..	++ to ++++	++ to +++	− to +++	− to +
" OX 2	++ to +++	++ to +++	− to ++	− to +
" OXK	− to +	− to +	− to ++	++ to ++++
Rash	Small macules, first on sides of chest, spreading over trunk, arms, and legs. Seldom on palms, soles, and face	As in louse typhus, but often inconspicuous or absent	Often conspicuous; may be nodular. Common on palms, soles, and face	Macular; often on face, rare on palms and soles
Local sore and lymphadenitis	Absent	Absent	Usually absent, but common in some localities, especially North and South Africa	Usually present in Japanese cases: absent or uncommon in Malayan and Dutch East Indian cases
Case mortality	5 to 50%	0 to 4% as a rule	1 to 70%	1 to 60%
Cross-immunity in animals	Strong against flea typhus, *nil* or weak against tick or mite typhus	Strong against louse typhus, *nil* or weak against tick or mite typhus	Only slight against other forms of typhus	Only slight against other forms of typhus
Distribution	Cosmopolitan, but not common in the Tropics	World-wide, common in the Tropics	Many localities in America, Europe, Africa, and Asia. Not common near the Equator except at high altitudes	Far Eastern tropical and subtropical countries

---

A case of insulin resistance has recently been described by E. Lozinski and L. I. Frohlich (*Canad. med. Ass. J.*, 1942, *46*, 62) in which 3,000 to 4,000 units of insulin daily were required to prevent hyperglycaemia, acidosis, and coma. Experiment failed to demonstrate any anti-insulin substance in the patient's serum. The pituitary gland was thereupon irradiated with *x* rays. One month after leaving hospital (i.e., 3½ months after the beginning of irradiation) the required insulin dosage was down to 500 units. Approximately 16 months after irradiation fasting blood sugar was 108 mg. per 100 c.cm. on a dosage of 40 units daily of zinc-protamine-insulin.

THOMAS MANN ON FREUD

BY

Sir WALTER LANGDON-BROWN, M.D.

Shortly after the last war Thomas Mann, then undoubtedly the greatest literary influence in Germany, produced a striking essay entitled *Freud's Position in the History of Modern Thought.* It does not appear to have excited much interest at the time, but it is so prophetic in tone, so penetrating a study of German mentality, and so appreciative of Freud's value as physician to the body politic, that his essay gains fresh interest at the present juncture. He starts by adopting Nietzsche's view that the later part of the 19th century was characterized by two leading *motifs*—reaction masquerading as progress, and subservience of reason to emotion. Though not confined to Germany they were specially potent there. He elaborates this by maintaining under the first heading that reformations by their very nature may have little to do with progress, since they tend to re-establish the old in an extremely conservative sense, and that at a time when the new is already known, while the second arouses sympathy with the chthonic and daemonic, with night and death—in short, with a primeval and earth-born religion. This recognition of the feeble control exerted by the reason and intellect, and of their incapacity to condition life, has led to scorn being poured on reason as an unfruitful illusion, and to the re-instatement of the irrational and instinctive. When reaction disguises itself as revolution, it succeeds best with youth, which not being fortified by experience against such tricks can be beguiled into accepting the most outworn devices as promising novelties. The revolutionary freshness of youth has impressed upon it the "principle of mindless nature, the folk soul, hatred, war . . . the great retreat dressed out in the uniform of the advance guard. . . . Is youth really going to fall victim to this crude abuse of the new knowledge? . . . We are no longer strangers to the disheartening sight of youthful bodies in gay quickstep, songs arising from young life, arms flung in a Roman salute, wasting the fine flight of their youth upon hoary ideas." Since he wrote those words history has answered his questions. As Kerr Clarkson expressed it in his *Europe in Eclipse,* Hitler's "Youth Movement was his method of harnessing the challenging demands of puberty to the service of the State," while Howard Smith in his vivid *Last Train from Berlin* concluded from study on the spot that the Nazi "Ship of State has ridden the waves, not of the future, but of the blackest past." Hitler has completed what Wagner began—the exploitation of the myth.

The recent arrest of the veteran physiologist Prof. Lapicque in Paris and the suppression of the *Presse Médicale* are typical of much. Science, literature, and art are to be tolerated only in so far as they are within the comprehension of the autocrat. Any higher values are met with the retort of Goethe's Mephistopheles—"I am the spirit that denies."

Indeed we must admit that a reactionary element is not uncommon in revolutions. The lictors' rods are suitable symbols for Fascism, for the Romans have been the most persistent *laudatores temporis acti* in all history, even in the moments of their greatest conquests. The renaissance of Irish nationalism gained force from the Celtic twilight, represented poetically by W. B. Yeats and pictorially by his brother.

Thomas Mann sees in Freud's technique a method designed to expose reactionary manœuvres. "Long ago, and certainly to the surprise of its physician-founder, it outgrew the domain of medicine and became a world-wide movement that has penetrated into all possible fields of intellect and science. . . . But being by origin a technique of healing, it has preserved in the broader intellectual fields its physicianly character, its human and ethical urge . . . which gives it a peculiar status within the scientific movement of our time." While Freud recognizes the power of impulse over the mind, he is far from giving way to its superiority, for, as he himself phrased it, "The voice of the intellect is low, but it rests not until it gets a hearing. In the end after countless repulses it gets one after all." When Freud describes the impulses to death and destruction as the effort of the living to relax the strain by returning to lifelessness, and then crosses this backward urge with the "actual life impulse"—namely, sex—with which all striving towards evolution is bound up, he gives to sexuality a revolutionary and intellectual significance such as had never before been ascribed to it. Extending his views from the individual to the body politic, Freud compares the unstable equilibrium of civilization to the condition in which a neurotic patient, without the will to recovery, comes to terms with his symptoms. This application of the idea of repression, leading to transformation into the neurotic symptom, to the disease of nations to-day I ventured to emphasize in my Maudsley Lecture in 1936. The modern fanatical outburst of nationalism may be regarded as the pathological outcome of repressing the evolutionary trend towards internationalism.

Mann thinks deeply, though perhaps at times almost too subtly, and not all will agree with him; nevertheless I feel that his diagnosis here is correct, and it is to be hoped that his anticipations of the therapeutic benefits to be derived from Freudian doctrines may be justified. He certainly concludes on an optimistic note: "The goal of psycho-analysis is a new life order, earned by effort, resting on freedom and security, obtained through self-knowledge. . . . It deals with the night, the dream, impulse, and the pre-rational . . . but it is far from being a tool of the obscurantist, fanatical, backwardly directed spirit. . . . It is, in my sincere conviction, one of the great foundation stones of a structure of the future which shall be the dwelling-place of a free and conscious humanity." Yet one feels impelled to add Crichton-Miller's observation as a *caveat*: "To Freud there are but two goals in life—libidinal satisfaction and a return to the inanimate. Jung on the other hand seems to see in human behaviour a manifold purpose which embraces realization of individual potentialities, mastery over circumstances and progressive evolution of the race."

TUBERCULOSIS IN WARTIME

We print below a summary of the main findings and recommendations of the M.R.C. Committee on Tuberculosis in Wartime. The following are members of the committee: Viscount Dawson of Penn (chairman), T. Stenner Evans, Prof. Major Greenwood, F. R. G. Heaf, G. Gregory Kayne, Sir Alexander Russell, Miss May Smith, Norman F. Smith, Wing-Cdr. R. R. Trail, Prof. G. S. Wilson, and P. D'Arcy Hart (Secretary). A leading article on this report appears at p. 429.

Summary of Findings

1. There has been a real increase in deaths from tuberculosis since the beginning of the war.

2. All age groups have been involved to some extent in the increase, and the participants up to the present have not been predominantly young women—as seemed likely early in the war—but include, particularly recently, children and the older male age groups as well.

3. Although there has been a slackening in the increase of tuberculosis mortality in the second year of the war—e.g., in young adult females—the position is still unfavourable in relation to the pre-war figures.

4. In view of the similar, though only temporary, slackening in the rise of tuberculosis at a corresponding time in the last war, together with what is known of the course of tuberculosis, we must be prepared for a further increase as hostilities continue.

5. A disquieting feature of the present position is the increased mortality of children from tuberculous meningitis. Measures have been indicated which should reduce the deaths from bovine infection. To reduce human infection it is necessary not only to take special measures with children, but also to control pulmonary disease in the adult. The suggestions which have been made for the early detection, segregation, and adequate treatment of the tuberculous adult should have an indirect effect in reducing infection among children.

Summary of Recommendations

Mass Radiography.—1. Subject to limitations of apparatus, the controlled use of mass radiography before, or as soon as possible after, employment should be extended, especially (*a*) in the Services, (*b*) among men and particularly women entering the war industries, and (*c*) among those taking up certain other occupations.

2. A single mass *x*-ray examination should be carried out, where practicable, upon those already employed in certain industries—e.g., munition factories.

3. As an extension of the preceding, but probably practicable to a much less extent in wartime, *x*-ray examinations should be repeated at regular intervals upon certain groups of the population, including (*a*) employees in factories which contain large numbers of young adults, (*b*) nurses and medical students, and (*c*) merchant seamen.

4. Where speed and cost dictate, the miniature method is the one of choice for mass radiography. In certain circumstances it may be practicable to make use of existing full-size apparatus.

Institutional Accommodation.—5. Accommodation for institutional treatment of tuberculosis is urgently required. A good deal is now available, but cannot be used because of lack of nursing and domestic staffs. Until these staffing problems are solved, no advance can be made in institutional control of the disease.

Financial Provision.—6. In view of the special character of the disease and the prolonged treatment usually required, special financial provision greater than that obtainable under the N.H.I. scheme should be made for persons with tuberculosis.

Rehabilitation.—7. Rehabilitation should be considered an essential part of the treatment of tuberculous persons, and arrangements should be made for the gradual return to industry of such patients on a basis of part-time or modified work. During the period of rehabilitation a supplement to wages should be provided, in order that an adequate standard of living can be maintained by the patient and his family.

Examination of Contacts.—8. The examination of all home contacts must be energetically pursued, a first examination being the chief requirement. The re-examination of children under 5 years of age, and of young adults, is highly desirable.

Examination in Special Cases.—9. *X*-ray examination, and re-examination at intervals, should be undertaken for all cases of pleurisy and erythema nodosum in young people, whether institutional treatment has been given or not.

Mental Hospitals.—10. The special conditions prevailing in mental hospitals make it desirable that an effort should be made as soon as practicable to *x*-ray periodically all residents of such institutions.

General Working Conditions.—11. It is of the first importance that continued watchfulness should be maintained upon the working conditions of young employees, particularly in regard to hours of work, transport difficulties, rest periods, factory canteens, and hostel arrangements, and their relation to sickness absence.

Milk.—12. The pasteurization of milk should be extended throughout the country, and, where this is not practicable, all milk consumed by children should be boiled, or dried milk should be provided.

Propaganda.—13. The implementing of these recommendations should be accompanied by information and propaganda both to the medical profession and to the general public.

SURGICAL HONOUR FOR LORD NUFFIELD

A ceremony was held at the Royal College of Surgeons of England on Sept. 30, when Lord Nuffield received at the hands of the President, Sir Alfred Webb-Johnson, the Honorary Medal of the College, a distinction instituted in 1802 for "liberal acts or distinguished labours, researches, and discoveries, eminently conducive to the improvement of natural knowledge and of the healing art." This was the eighteenth award, and earlier recipients had been Lord Lister, Sir James Paget, and Sir Richard Owen. The company supporting the President and the Council in the College building at Lincoln's Inn Fields included Mrs. Churchill, representing the Prime Minister in his capacity as First Lord of the Treasury and Trustee of the Hunterian Collection; Mr. Ernest Brown, Minister of Health, and Miss Horsbrugh, Parliamentary Secretary to the Ministry; Sir Charles Wilson, President of the Royal College of Physicians; Dr. Daniel O'Brien of the Rockefeller Institute; Sir Farquhar Buzzard, Regius Professor of Medicine at Oxford; Mr. H. L. Eason, President of the General Medical Council; and Sir Stanley Woodwark, Master of the Society of Apothecaries.

The President welcomed the distinguished company whom the prestige of the Royal College of Surgeons and the romance of this occasion had brought together. The primary duties of this corporate body were the same to-day as those of their fathers of old—to strive for the improvement of the science and art of surgery, and to ensure that those who practised it were qualified to do so. It was essential that it should continue to be an arbiter of surgery and a centre of independent authority. While keeping in the van of progress it had to preserve the broad bases on which the whole edifice of biological knowledge was built, thus maintaining it as a great staff college of learning. Besides being heirs to these responsibilities and traditions the Council were trustees of several distinctions and awards; one of these was the Honorary Medal. Lord Nuffield's youthful ambition to be a surgeon was not to be fulfilled, but they had invited him to the headquarters of British Surgery that day to receive their most exclusive emblem of merit in recognition of his greatness in generosity and in wisdom.

The Senior Vice-President, Surgeon Rear-Admiral G. Gordon-Taylor, presenting Lord Nuffield for the award, said that it was not only the dazzling magnitude of his gifts to medicine but also the manner and the direction of his giving that the College wished to honour—the thought and the deliberation that had guided each beneficent act. The whole realm of the healing art had attracted Lord Nuffield's interest and had come within the orbit of his wise munificence.

Lord Nuffield, in a brief acknowledgment of the medal, said that nothing he had ever received had given him greater pleasure. What he had done for medicine and surgery was only what he thought he should have done, and it would be his highest ambition and desire in the future, as in the past, to help those less fortunately placed than himself, and to encourage others to do so.

Mr. Ernest Brown, at the close of the ceremony, spoke in praise of Lord Nuffield's gifts, saying that too often givers who lavished money on expensive buildings showed little concern for the men and women who were to work in them. Lord Nuffield never made that mistake. Of all his gifts the Minister would like to praise him most for two things—the establishment of the Professorships and Readerships at Oxford, and the foundation of Chairs of Social Medicine and of Child Health.

AWARD FOR GALLANTRY

Dr. ROBERT HAMILTON MOYES, deputy medical officer of health, Kingston-upon-Hull, has been appointed an M.B.E. (Civil Division). The citation in the *London Gazette* reads:

> "Throughout enemy air raids Dr. Moyes has played an important part in succouring wounded and trapped people and in encouraging the personnel of civil defence services. During one raid he rendered assistance to many victims and gave morphine to ease the sufferings of those who could not be immediately released. This necessitated crawling into tunnels at a time when debris was still falling, but he carried on regardless of personal risk and displayed a high degree of courage. His initiative and skill undoubtedly saved several lives and brought comfort to the suffering. Dr. Moyes has been medical officer at many incidents and he has always maintained a high standard of professional skill and courage. He has worked untiringly for the injured victims of enemy air attack and his calm demeanour has been an inspiration."

A conference of the Nutrition Society will start at 11 a.m. at the London School of Hygiene, Keppel Street, London, W.C.1, on Saturday, Oct. 17, to discuss "Trace Elements in Relation to Health." Papers will be read by Dr. H. H. Green (Significance of Trace Elements in Relation to Diseases of Plants and Animals), Dr. R. L. Mitchell (Distribution of Trace Elements in Soils and Grasses), Prof. D. Keilin and Dr. T. Mann (Copper, Zinc, and other Trace Elements in Relation to Physiological Function and Enzyme Systems), Prof. T. Dalling (Enzootic Ataxia or "Swayback" of Lambs in England in Relation to Copper Feeding of Ewes during Pregnancy), Sir Charles Martin (Cobalt and Other Trace Elements in Relation to Disease in Australasia), Dr. W. Lyle Stewart (Sheep "Pining" in Britain), Dr. M. M. Murray, Dr. D. C. Wilson, and Dr. F. H. Kemp (Fluorine in Human Nutrition), Mr. F. Blakemore (Industrial Fluorosis of Animals in England), Mr. W. S. Ferguson ("Teart" of Somerset; a Molybdenosis of Farm Animals), Dr. R. A. McCance and Miss E. M. Widdowson (Absorption and Excretion of Trace Elements). Further details of the Nutrition Society can be had from the Hon. Secretary, Dr. Leslie Harris, Dunn Nutritional Laboratory, Cambridge.

Correspondence

Dysentery and Diarrhoea in Wartime

SIR,—Sir Philip Manson-Bahr's paper concluded in your issue of Sept. 26 (p. 374) will be helpful to many medical officers in the Services and elsewhere. But in recommending doses of 50 to 80 c.cm. of serum in severe cases of Shiga dysentery he is not, I think, taking into account the remarkable progress achieved during the past few years in refining and standardizing these sera. The product issued to the Army contains 50,000 international units of antitoxin in a volume of less than 10 c.cm.: and 50,000 to 100,000 units is considered sufficient as an initial dose, even in fulminating toxic cases, if given intravenously. Intravenous injection, as Sir Philip will agree, is preferable to intramuscular injection as a means of securing rapid circulation of antitoxin; and, thanks to the use of proteolytic enzymes in preparing the serum, the risk of anaphylaxis to which he refers is now so small that it need no longer deter us from using the most effective route.—I am, etc.,

War Office, S.W.1

L. T. POOLE,
Major-General, Director of Pathology

Post-mortem Facilities for All

SIR,—Prof. G. Grey Turner's letter (Sept. 26, p. 376) on post-mortem facilities for all seems to be based on a misunderstanding. He refers to post-mortems in cases connected with workmen's compensation, but in all such cases where an accident has occurred it is the duty of the doctor to notify the coroner. A complete necropsy will then be ordered. And, again, when persons have died after discharge from hospital and where the cause of death is not known, the doctor should inform the coroner so that a post mortem can settle the question.

In other words, the essentials for which Prof. Grey Turner craves are already in existence and in action; but, admittedly, the "fully equipped institutes" do not exist. If they did, they would be but rarely required because in the great majority of the cases to which Prof. Turner refers the simple methods of the morbid anatomist (and histologist) suffice; on the rare occasions when they do not, the hospital laboratory is available for complicated investigations.—I am, etc.,

London, W.1

A. PINEY.

Antiseptic Technique

SIR,—We would like to associate ourselves with Prof. R. J. Willan's plea for an antiseptic technique in surgery (Sept. 5, p. 291). His letter has prompted us to give an account of our own experience. After discussions last February, we decided to try to eliminate rubber wastage by adopting the following technique for scrubbing-up in the theatre, and have used it exclusively ever since.

1. Ordinary toilet of nails, etc.; wash hands and forearms and dry.
2. Put on non-sterile rubber gloves previously inspected and patched if necessary. The gloves should be well pulled on to obviate wrinkles and the risk of resultant unwashed areas
3. Wash gloved hands in soap and water for three minutes.
4. Put on sterile gown and fasten the sleeves at the wrists over the gloves with small rubber bands previously sterilized in 1 in 50 lysol. The gown sleeves should be long to avoid exposing areas of bare wrist.
5. Steep hands in 1 in 50 lysol for two minutes.
6. Rinse in saline.

Using this technique more than 2,000 operations have been performed in the past eight months, of which 800 were major operations. This number includes some 700 abdominal cases of various kinds, but does not include 121 operative obstetric cases, for which the above technique has also been used exclusively. No difference in the wound-healing and post-operative progress has been observed between this technique and the usual aseptic method using dry-heat-sterilized gloves.

Our justification for bringing this procedure to your notice is: (*a*) That it prevents the wastage of rubber gloves caused by heat sterilization. This saving of gloves has been so marked that consumption has been reduced to one-eighth of the previous quantity. In addition, the gloves fit as perfectly after five weeks' use as when new, the only reason for their final abandonment being the impracticability of patching them further. (*b*) The technique is applicable should war conditions abolish the sterilization amenities of a modern theatre.

We agree with Prof. Willan that operations can be performed successfully with an antiseptic technique and no gloves at all, but gloves afford a necessary protection to the surgeon against infection.

Our experience gives us complete confidence in recommending this method to other surgeons, and we regard the marked saving of rubber as a definite war economy.—We are, etc.,

Classification of Nerve Injuries

SIR,—It may cheer Dr. Russell Brain to know that I have received three other letters of complaint about the terms recently introduced for the three types of nerve injury. All the correspondents have suggested others—some old, some new—but with one partial exception the only thing common to their terms is that they are not so un-English as "neurotmesis," "axonotmesis," and "neurapraxia." In my opinion none of them (except, perhaps, "division") is satisfactory. There has, in fact, never been agreement on the nomenclature of nerve injuries, although I believe that in their own minds most neurologists are fairly clear about the three main types. But I cannot help being a little doubtful about Dr. Russell Brain. In his excellent textbook of neurology (1940) he draws no clear distinction between them, and in referring to the second type as "division of axis cylinders without division of the nerve sheath" (this was not my description) he has failed completely to appreciate the importance of the survival of the more intimate supporting structures of the nerve. Preservation of the sheath alone is of little value so far as spontaneous regeneration (a constant feature of axonotmesis) is concerned, as we have demonstrated histologically. And he does not use his own or any other terms in his book.

It is necessary, first, to ask whether he wishes the terms, his or mine, to be used in the widest possible sense or to refer only to lesions produced by certain kinds of injury. It seems to me that the more comprehensive a term the greater its value. Secondly, the term should be more closely related to effect than cause, and the effect should, where possible, be indicated in such a way that the reader is made aware of the consequent anatomical and functional disturbances. I do not suggest for a moment that this should be a universal rule, but it applies with great force to most local lesions and especially to nerve injuries.

Let us consider Dr. Russell Brain's *contusion*, "injury by blow without breaking the skin" (*O.E.D.*). This is much more a description of the cause rather than the effect, but, as the Table shows, axonotmesis may be produced in at least eight different ways, and in each the result is the same. The word "axonotmesis" indicates that the axons have been divided; a little thought brings one to the conclusion that the disturbance

Neurotmesis	Axonotmesis	Neurapraxia
1. Open wounds	1. Open wounds	1. Open wounds
2. Direct-blunt injuries	2. Direct blunt injuries	2. Direct blunt injuries
3. Traction	3 Traction	3. Traction
	4. Compression, sudden or prolonged	4. Compression, sudden or intermittent
	5. Friction (? a combination of 3 and 4 as in traumatic ulnar neuritis)	
	6. Freezing	5. Freezing
4. Local chemical poisoning	7. Local chemical poisoning (e.g., injection of sulphapyridine)	6. Certain drugs
	8. Experimental crushing	7. Experimental compression

In other words, there are more ways of

producing {neurotmesis / axonotmesis / neurapraxia} than by {dividing / contusing a nerve / concussing} of function must be exactly the same as if the whole nerve had been divided (hence the importance of the cognate neurotmesis); and a little experience reveals the striking difference between the two when recovery occurs—namely, that axonotmesis, being predominantly a simple break in the axons, is capable of spontaneous regeneration, whereas neurotmesis is not. "Contusion" is, therefore, a limited, vague, and thoroughly unsatisfactory term.

And so is "concussion." How does "a violent shaking" (*O.E.D.*) fit the six or seven known causes (see Table) of neurapraxia? I admit that "neurapraxia" is a little unsatisfactory, but not for the reason that Dr. Russell Brain gives. The difficulty is that no constant anatomical lesion has yet been demonstrated, and hence it cannot be described. But we do know that the nerve (or certain fibres in it) stop working, and this is precisely what "neurapraxia" means. He is disturbed because "apraxia" is already used in medicine in another connexion. Apparently he takes to himself the privilege not simply of copyrighting a word (which is legitimate and is called definition) but forbidding its use as part of a compound. Why not command the anatomists to abandon "aponeurosis" because "neurosis" "has for many years been the name of a psychic disturbance at the highest level"?

I am not fond of new words, and I am especially shy of the strange terms, many of them of Greek origin, that have come into medicine during recent years, more particularly in neurology. But here there was a real need, and I think Prof. Henry Cohen has made a successful attempt to meet it. This is why my colleagues and I use these words. The fate of them will not be decided by their inventor, Dr. Russell Brain, or myself. If they express something that is true, or reasonably near the truth, and if they fill what is clearly an awkward gap in neurological nomenclature they will probably survive. If they are found deficient or perhaps just too difficult to pronounce then they will almost certainly perish.—I am, etc.,

Headington, Oxford. H. J. Seddon.

Treatment of Haemophilia

Sir,—The paper by Messrs. C. L. Endicott, J. H. Mitchell, and G. Qvist (July 11, p. 34), describing a fatal case of bleeding in a haemophiliac, has given rise to some subsequent correspondence. While we agree with Prof. G. Grey Turner (Aug. 29, p. 258) that suitable local measures should be employed when the site of bleeding is accessible, it would appear, as Dr. R. G. Macfarlane and Prof. L. J. Witts have admirably pointed out (Aug. 1, p. 140), that the value of *general* therapy in controlling bleeding in haemophilia is still not sufficiently appreciated. From a study of 6 haemophiliacs at the Hospital for Sick Children, Great Ormond Street, London, we demonstrated (*British Medical Journal*, June 29, 1929) that the only general treatment of any value in haemophilia is the intravenous administration of whole blood or plasma. We showed that this resulted in an immediate fall in the coagulation time to a normal figure, and while the figure rose steadily to its original level after about one week, the temporary improvement was sufficient to act as a most valuable haemostatic, and in our cases resulted in an immediate cessation of bleeding. As Dr. Macfarlane and Prof. Witts mentioned, other workers have confirmed these findings.

At the time our paper was published dried plasma was not readily available, but there is every reason to hope that it would be equally as efficacious as liquid plasma. At that time we approached a well-known firm to try to get human plasma in ampoule form, but we were told that owing to the rarity of haemophilia the demand would not make this possible. Now that blood and plasma are so readily available the difficulty has been largely overcome. We feel, however, that the impression may still be held that blood transfusion in haemophilia is simply trying to maintain a blood level which will continue to fall unless something further is done. We would therefore again point out that blood and plasma act in haemophilia as substitution therapy, supplying the missing factor, and analogous, therefore, to insulin in diabetes or thyroid in the cretin, except that in haemophilia the exact nature of the defect has not as yet been fully established.—We are, etc.,

London W. W. Payne.
Dublin. R. E. Steen.

Breast-feeding

Sir,—Prof. Charles McNeil in his interesting article on this subject (Sept. 5, p. 271) says in conclusion: "Every doctor and nurse who has the responsibility of advising and assisting mothers in breast-feeding ought to urge its continuation wherever possible and as long as possible, and give their best thought and effort to overcome any difficulties that may arise." The question at once prompted to my mind is: "How are these difficulties to be overcome?"

So far as I can see the most difficult and dangerous period for the mother and child in this effort to breast-feed is the four weeks following the return home from the nursing home or after the midwife and/or the doctor have ceased visiting the house. The mother, who has received scanty grounding in the art of breast-feeding during the short preceding fortnight, is now left to her own devices, surrounded by various members of her family and her omniscient neighbours. It may be that she has been fortunate, that she has good feeding breasts, plenty of milk, and a healthy, normal-sized, tractable, good sucking baby. Under these conditions she usually requires and seeks no advice and may be seen neither at the clinic nor by her own doctor until the first disturbance of health demands advice.

The mother may, however, fall into the category of those who have no wish to feed their babies, upon whom it is not worth wasting time, or of those who find difficulties in the task but who, rightly advised, will succeed in overcoming them. Very frequently she fails because: (1) she is overridden by her friends' advice, or (2) because she finds bottle-feeding a way of escape from what appears, with insufficient practical help, an impossible task with its attendant anxiety state. The help she requires in this difficult period must be given frequently, unhurriedly, and in the home, and it is most likely that before the problem is solved there must be opportunity for a number of test feeds. It is my opinion that such help, in the present state of things, is not and most likely cannot be given by the infant welfare clinics or the health visitors. It cannot be given by the former, because over an anxious period weekly visits are useless, for in the meantime the fight may be lost and submission made to bottle-feeding. It cannot be given by the latter, because most of their time is taken up by shepherding the legions of babies at overcrowded clinics whose mothers have come (*a*) to weigh the baby, (*b*) to get artificial foods cheaply, or (*c*) to spend a pleasantly gossipy hour. Each of these babies occupies the time in turn of the caretaker, the voluntary worker, one or two health visitors, and the doctor. Individual attention is impossible and often not encouraged by those in authority, and the criterion of success is numbers. Even if the health visitor does find time and is allowed to tear herself away from the clinic to do a useful bit of follow-up work at the home of a difficult case, the length or frequency of the visits is often insufficient to be really effective.

Could not a great deal of what appears to be wastage of time and effort at the clinics be given to home visitation in the early days of difficult cases, or could not one health visitor at least be available each day at the public health department, to whom harassed and anxious mothers could come for advice if they have no doctor to whom they could turn, or if the economic factor prevents their doing so? Some babies can feed from any mother and some mothers can feed any baby. Let all such visit the clinic less often and so allow those responsible to concentrate on the doubtful difficult cases.

It may be that in some areas this problem has been tackled and some such arrangements have been made. If so, I apologize for any apparent generalizing aspersions I may have made, and ask any who have solved this problem to give others who have not the benefit of their knowledge and experience.—I am, etc.,

London, S.W. E. Gerard Housden.

Sir,—With regard to the establishment of natural feeding, it has been my experience in many different areas that those mothers who are attended by the district midwives, although from much poorer and less well-fed homes, show far greater success than those who are admitted to hospital. I am certain that this is due to the misguided interference on the part of their medical advisers. Expectant mothers should be taught that pregnancy, childbirth, and lactation are normal episodes in a woman's life, and should be taken in her stride. So much stress is often laid on preparation for breast-feeding that the mother comes to think of it as something difficult to achieve and literally "worries the milk away." Another unfortunate mistake is that of the maternity hospital sister who is over-anxious to get the baby's weight up to a prearranged standard before its discharge. She frequently tells the mother how much it has gained at every feed, and is far too ready with the complementary feed. It cannot be too strongly stressed that, short of actual starvation, the baby should be left alone in its earliest days (except for extra water); as it becomes hungrier it will suckle more vigorously and stimulate the breast.—I am, etc.,

L. M. M. Beadnell,
Assistant Medical Officer, Maternity and Child Welfare, Barking

Fair Distribution of Milk

Sir,—Last autumn all general practitioners were asked to assist the Ministry of Food in its endeavour to direct the available supplies of liquid milk to those needing it most. On the advice of the Special Diets Advisory Committee, the Medical Research Council, and the B.M.A., arrangements were then made whereby doctors could prescribe quantities up to 2 pints a day for certain specified types of invalids. In a letter I received on this subject from the Ministry of Food last autumn I was informed that if the maximum allowance be prescribed in every case of illness qualifying for priority milk the total amount consumed in this way would seriously curtail the supply available for able-bodied adults, and even prejudice the quantities needed by mothers, children, and adolescents.

The Ministry of Food asked for and readily obtained our co-operation in maintaining a proper balance between the claims of the healthy and the sick upon our milk supply. However, a new form of milk certificate has now been issued (R.G. 50) and been in use for at least a month, and we are now not asked to prescribe any definite quantity of milk for our invalid patients. The question of quantity is governed entirely by the class or category in which the patient is placed. Thus, a patient suffering from an acute form of gastric ulcer, confined to bed, and living almost entirely on milk, receives a certificate that he should be granted "such supplies as are at present authorized." In this case he is placed quite rightly in Class I of the schedule of diseases, and the local food control office will give him automatically an authority to obtain the maximum of 2 pints a day. However, a patient suffering from a chronic form of the same disease, not confined to bed, and able to take a varied diet, yet needing extra milk, receives under the regulations exactly the same certificate, since he has to be placed in the same class and consequently obtains an authority for the maximum quantity. As the need for milk in the acute and chronic cases is very different, it would seem that unless something is done to amend speedily the present form of certificate, the available supplies will not be directed fairly to those needing it most.—I am, etc.,

J. D. Borham,
Medical Officer of Health, Southwold

Rickets on the Increase

Sir,—In recent months during the clinic sessions of an extremely widespread and well-supported orthopaedic service I have been convinced that there is a definite increase in the evidences of rickets. This has been thoroughly investigated and the results are as follows: (1) there is a 50% increase in the number of rachitic patients seen; (2) a 15% increase in the number of cases of acute rickets: these have been of a much more severe type than formerly; (3) very many cases are in babies of 4 to 8 months of age. In the majority of these cases vitamin therapy has been used, and with regard to the babies, all of whom were breast-fed, the mothers had not been taking vitamin D.

May I submit my conclusions; they are: (1) the present standard of dosage of vitamin D is inadequate; (2) more care should be taken of nursing mothers; (3) there should be some form of notification of every case of acute rachitis; (4) a thorough, widespread investigation should be carried out if other centres report similar findings.

My period of investigation has been from March to September for the years 1941-2. It has in most cases been impossible to ascertain when symptoms first began, so sunlight estimations have not been practical, but in the gross majority the parents have assured me their children get plenty of fresh air.

With regard to notification, I feel it is only in this way that rickets can be placed in its rightful category of seriousness. Certainly notification should make possible investigation by the local health service. Rickets, with its distressing sequelae, is a preventable disease, and in my opinion every case is a responsibility, if not a disgrace, on our medical organization. —I am, etc.,

Manfield Hospital, Northampton. Noël Smith.

Tenosynovitis in Untrained Farm-workers

Sir,—It is with great interest that I read the report of Colonel Flowerdew and Dr. Bode on this condition (Sept. 26, p. 367). At this time of the year, here in Kent, we all go to the hop-gardens, joining those who come to spend their holidays hop-picking. For the uninitiated, hops are about the size of a rose-bud and the texture of tissue paper, and a good picker might gather 30 to 35 bushels a day. Every year, a few days after picking has started one sees at least half a dozen cases of tenosynovitis, always affecting the extensor tendons, usually the extensor ossis metacarpi pollicis and the extensor digitorum communis. For these patients hop-picking is finished for that year. Treatment has always consisted of strapping with elastoplast and complete rest for a week and restrapping for a further week. Recovery is the rule at the end of this time, and these workers are able to pick the following year, usually without recurrence.

I believe that it is the repetition of exactly the same movement many hundreds of times a day that induces the inflammation, for it is often the experienced picker, "out to do a little better this year," who is affected, and not the novice picking but a few bushels a day.—I am, etc.,

Tenterden. Thos. H. E. Taylor-Jones.

The Demand on the Blood Donor

Sir,—Your leading article on the demand on the blood donor (Sept. 19, p. 342) interested me. When, ten days ago, a donor previously bled 5 months before presented herself to me for bleeding and on investigation I found her to have only 60% haemoglobin (Sahli), instead of bleeding her I gave a prescription for iron on a hospital form; I told her to continue with iron therapy for 6 or 8 weeks, assuming that she would quite cheaply obtain the iron in the form prescribed from a local chemist, there being no out-patient facilities within 10 miles of her home. She, however, went to her family doctor, who upbraided me on the telephone for not referring her in the first place directly to him. I thought he had reason for complaint on ethical grounds, though from the donor's point of view—i.e., convenience and expense—and from the point of view of preventive medicine in general, I considered that I may have done rightly.

I then ascertained the official view of my own transfusion service, and it was that enrolled donors should be at liberty to accept free advice and if necessary prescription of iron from the transfusion officer attached to the service in which the donor is enrolled—this has been its custom from inception 18 years ago. In the leading article there appear the following passages: (1) "Transfusion officers are beginning to realize the need for checking the haemoglobin level before bleeding and for prescribing iron for the prevention and treatment of anaemia in blood donors." (2) "It seems unwise to bleed a donor whose haemoglobin is below 11.7 g. per 100 c.cm., or 85% on the Haldane scale. Such volunteers should be advised to take iron and be seen again after an interval. For administrative reasons, it may be simpler to prescribe iron for all donors after bleeding."

There is no doubt in my mind which of these methods is likely to be most effective in preventing anaemia, especially as moderately anaemic subjects are virtually symptomless very often, and are, therefore, unlikely to seek professional advice in more than a percentage of cases, even when this course is suggested to them.—I am, etc.,

Sutton Coldfield Guy R. Bashford.

Sir,—With reference to your leading article (Sept. 19, p. 342), I think the following case will be of interest.

A patient, a woman of 26, has been acting as a blood donor for the last 3 years. She has been called upon every 3 months up to April, 1942, during that period. The last time she was called upon, in July, 1942, she did not attend. She was sent to me by her private doctor in August, 1942. There was evidence of chronic disease in the left lung and the sputum test was positive. She gave a history of having had a cough for the last 3 years. There was no history of tuberculosis in the family, and considering the factors that lead to the manifestation of tuberculosis importance can be attached to the fact that she has been a regular blood donor. Further study, however, of her dietetic habits revealed the fact that she was the type of individual who disliked meat and fat, cabbage, and green salads. The lack of these elements in her diet would cause a state of malnutrition, and this condition would be intensified by the regular withdrawals of blood.

The advice given in the article, that volunteers should take iron, is good, but it also seems necessary that inquiry should be made into the habitual diet of these volunteers, and that they should be investigated by miniature radiography.—I am, etc.,

Plaistow, E.13

P. A. Galpin,
Tuberculosis Officer.

"Silent" Sinusitis

Sir,—I wish to confirm Mr. Terence Cawthorne's statement (Sept. 26, p. 379) that sinus disease as a cause of visual disturbance is very rare. It has been and is my privilege to see a number of cases of retrobulbar neuritis and loss of sight referred to my clinic by one of our largest ophthalmic hospitals. In 1923 I studied my notes of 54 cases of retrobulbar neuritis; after a careful and thorough examination of the nasal sinuses, in only 5 of the 54 cases was the retrobulbar neuritis due to nasal disease (*British Medical Journal,* Nov. 10, 1923). Many of these 54 cases were followed up, and at a meeting of the Sections of Ophthalmology and of Laryngology in 1926 (*Proc. roy. Soc. Med.*, 1926, vol. 19, Sect. Ophthalmol., p. 90) I gave details of the review of 76 cases of optic neuritis, and in only 5 of these was the neuritis caused by nasal disease. In all these 5 cases the sinusitis was manifest and obvious.

Modern methods of examination and improved *x*-ray photography have abolished latent, hidden, or silent sinusitis, and to the honest rhinologist "silent sinusitis" does not exist.

My experience since the above publications in 1926 has shown that the number of cases of loss of sight of nasal origin are considerably fewer than the above figures indicate.—I am, etc.,

London, W.1. Edward D. D. Davis.

Sir,—It is only right to be sceptical about a condition which is difficult to diagnose except by a specialized *x*-ray technique not always available. I felt sceptical myself when first introduced nearly 3 years ago to the Proetz technique of ephedrine replacements as a means of curing asthmatics, epileptics, and "migraines." The proof of the pudding, however, is in the eating.

A boy of 14 was seen in May, 1940. He had had asthma since an attack of measles in 1936. He was deaf and "bunged up" with catarrh. He had 12 replacements over about 3 weeks. His catarrh and deafness cleared up completely, and he has had no asthma since.

A youth aged 19 suffered from petit mal, having had an attack about once a fortnight since childhood. He had a stuffy, blocked-up nose. He had 10 replacements in June, 1940, and has not had a single fit since.

These two cases are selected from a large number, all of which have shown remarkable improvement by relieving this allergic condition of the sinus linings.—I am, etc.,

Ashtead, Surrey. W. Edwards.

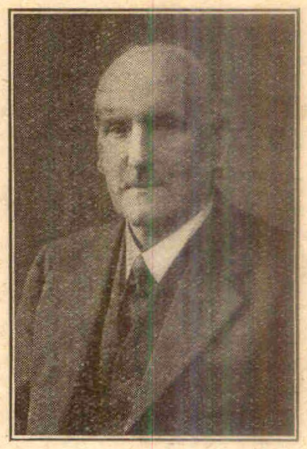
Sir,—Mr. Terence Cawthorne (Sept. 26, p. 379) writes of the custom to regard the sinuses as healthy in the absence of radiological or clinical evidence. In the face of the evidence given in the two cases I reported in the *Journal* of Aug. 1 (p. 128), is it not time that we changed our custom?—I am, etc.,

London, W.1. Rosa Ford.

Obituary

A. B. MITCHELL, O.B.E., F.R.C.S.I., M.P.

The recent death of Arthur Brownlow Mitchell (familiarly known to all old Queensmen as "A. B.") has severed a link which securely bound successive generations of medical graduates to Belfast for half a century.



Entering the old Queen's College as a medical student in 1885, he graduated in the Royal University of Ireland in 1890. By winning the Coulter Exhibition he had already proved himself the first man of his year and had given an indication of that ability, industry, and practical knowledge of medicine and surgery which in later years placed him in the forefront of the surgeons of his time. After graduation he held the post of house-surgeon to the Royal Hospital at a time when there were but two resident medical officers. At once he showed his dexterity and quickness in the performance of minor operations and in the treatment of fractures, and by conducting a surgical "grind" for final-year students gave promise of the capable and attractive teacher which remained one of his chief characteristics throughout his surgical career. In 1893 the Ulster Hospital for Children and Women gave him his first staff appointment, and this was followed next year by his election as assistant surgeon to the Royal. In both these institutions he had for a colleague William Whitla, for many years his chief medical friend. At this time both hospitals had become antiquated and ill fitted for the great advances which were to be made within the next few years. In the rebuilding of each Mitchell took a prominent part and showed that he possessed other qualifications for leadership besides those of a professional nature.

The time was opportune for the young surgeon. A new era had just been opened by the discoveries of Lister. These inaugurated the study of pathology in the living subject. The abdomen lent itself to this experimental stage both by reason of the extent of the field and by the relative ease with which abdominal explorations could be carried out. Mitchell was immediately attracted by its problems. His enthusiasm, manual dexterity, gentleness, and quickness gave him initial successes in gastric and duodenal perforations. Operations for acute appendicitis followed and afforded facilities for studying the varied pathology to which this organ gives rise. In a brief period Mitchell obtained a wide experience of abdominal diseases generally, and by papers on abdominal subjects to the various societies played a great part in the medical education of the Province. These papers established the position of the rising young surgeon throughout the whole country, notably enhancing the reputation of the Belfast Medical School. At the Belfast Meeting of the B.M.A. in 1909 he read a paper on 23 consecutive operations for perforations of the duodenum, with two deaths—a record performance at the time. The treatment of the "acute abdomen" by surgical methods was soon followed by the operative treatment of less urgent conditions. As pathological knowledge increased attempts were made to anticipate perforations of the stomach, duodenum, and appendix. This opened up a wide field both in diagnosis and treatment when *x*-ray diagnosis was still in its infancy. Gastro-enterostomy for pyloric obstruction is an obvious example of this, and few operators in the country equalled him in the performance of this operation. While the upper abdomen absorbed much of Mitchell's attention his technical skill gave him experience in all abdominal diseases, so that before 1909 he had contributed important papers on intussusception, intestinal obstruction, and cancer of the rectum.

Mitchell's outstanding position in the surgery of the abdomen in the early years of the century brought with it a rapid increase in his work as a consultant. His advice was sought not only by the general practitioners all over the country but by the surgeons to the county and district hospitals, most of whom were brought up on pre-Listerian principles and were eager for him to demonstrate his methods in the country. The advent of the motor car made this possible, and during the ten years before the last war Mitchell's country work was enormous. The outbreak of war showed, however, that he was a general surgeon of wide capabilities. He was nominated by the Royal College of Surgeons in Ireland for the post of consulting surgeon to the Forces in France. When the invitation arrived, however, he was in a nursing home, having himself undergone an abdominal operation. He had therefore most unwillingly to decline the offer. Later on, in 1916, Sir Robert Jones put him in charge of the Military Orthopaedic Hospital in Belfast. In this post he proved himself a first-rate administrator as well as an expert on the problems presented by the wounded soldiers who were arriving in great and increasing numbers. At this time his daily list included nerve sutures, bone grafting, and amputations. During the war the hospital dealt with over 3,000 cases, and this work gained for him the O.B.E.

But Mitchell's interests were not confined to his professional work. When Queen's College became Queen's University in 1908 he was appointed to the Senate. From the first he was a member of the Standing and Finance Committees, which determine the policy and carry out much of the administrative work of the university. For several years he was chairman of the Athletic Field Committee, and the spacious and attractive grounds at Cherryvale are a permanent memorial to his foresight and knowledge of the value of physical health to the student. In 1935 he became M.P. for the university in the Northern Ireland Parliament. He greatly appreciated the confidence of his medical friends which this honour conveyed, for he had never had time in his very busy professional life for political activities. In Parliament he often spoke on public health problems, especially when these entailed the improvement and extension of medical services. Whatever Mitchell's activities may have been, and they were widespread, he allowed nothing to interfere with his work for the Royal Victoria Hospital. At his retirement from the active staff he joined the board of management, and for twelve years up to the end held the office of chairman. Under his direction recent extensions were made to the wards, and the new fracture department now in process of building had his constant support.

Mitchell's greatest asset was the charm of his personality. His rapid success in his early surgical career did not fail to cause some jealousy. Most of this, however, was ill founded, and he lived to gain the undivided esteem and affection of his colleagues on the staff of the hospital and its board of management. He had many friends, too, among the leading surgeons of his time. Two of his most cherished possessions were letters of appreciation from Lord Moynihan and Sir Robert Jones.

Dr. **Edwin Lancelot Hopkins** died suddenly on Sept. 10 at the age of 53. He had been medical superintendent of the Derbyshire County Mental Hospital since June, 1931. E. L. Hopkins was a Somerset man, lived for some time in Southern Ireland, and studied medicine at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1916, after which he at once joined the R.A.M.C. and saw service first with the 39th Field Ambulance, and later with the 6th Battalion South Lancashire Regiment in Mesopotamia, being awarded the M.C. for conspicuous gallantry and devotion to duty while attending the wounded under fire. Upon the termination of his military service he secured an appointment in the Ministry of Pensions and took the D.P.H. in 1921, after which he joined the L.C.C. Mental Hospitals Service, and was A.M.O. at Bexley and Hanwell Hospitals, and deputy medical superintendent at the Ewell and West Park Hospitals at the time of his appointment to the Derbyshire County Mental Hospital at Mickleover. He was a man of charming personality, and displayed a kindly sympathy which endeared him to his patients and to those with whom he came in contact in his various outside activities. During his term of office at Mickleover he added much to the amenities of the patients, improving their living conditions and methods of treatment, and creating a fuller sense of security and freedom in the outlook of the mental sufferer. He inaugurated psychiatric clinics at Derby and Chesterfield and helped many neurotic subjects by his calm, kind, and tolerant attitude. He avoided hasty decisions and proved himself a man of sound judgment.

On Sept. 16 there passed away Judge **Digby Cotes-Preedy**, one of the few medical men who have forsaken medicine and thereafter attained distinction at the Bar. The outstanding instance in our time is the late Lord Finlay. He was born in 1875, and after taking his degree at Cambridge, from Emmanuel College, he studied at St. George's Hospital; but he always had one eye on the law, and this delayed his qualifying as L.S.A., about which he appeared to be in no great hurry. He held a house appointment at his own hospital, however, and was "called" not long after. Always a man characterized more by knowledge of the world than by aptitude for academic distinction, he applied himself to his second profession with great energy. He became law reporter for the daily press (actually, for the *Daily Mail*, if memory serves) and attended the Courts most assiduously. This, together with his natural shrewdness and native wit, with which he was well endowed, presently led him to adopt the Divorce Division as his province, and there he soon obtained a very considerable practice as a junior. In 1925 he took silk, and continued to enjoy even greater success, becoming a Bencher of the Inner Temple in 1932. He was promoted to a County Court Judgeship in 1936, but had to resign owing to ill-health in 1941. He had been a member of the Coroners Committee in 1935 and served on two select committees during the war of 1914-18. He was also Chancellor of the Diocese of Worcester. Cotes-Preedy was an interesting and amusing raconteur; and the County Court Bench was exactly his right *milieu*. He married in 1908 Margaret, younger daughter of the late Mr. S. Bradley of Blakedown, and had one son. His father was the late Rev. D. H. Cotes-Preedy, minor canon of Worcester Cathedral.

The Services

The M.C. has been awarded to Capts. A. A. Byrne, C. R. Tilly, E. Townsend, and J. Watt, R.A.M.C., and to Capt. R. B. Sule, I.M.S., for gallant and distinguished services in the Middle East.

Capts. J. H. Annan, A. C. D. Parsons, and I. McD. G. Stewart, R.A.M.C., have been mentioned in dispatches in recognition of gallant and distinguished services in the Middle East.

CASUALTIES IN THE MEDICAL SERVICES

Temp. Major **John MacMillan**, R.A.M.C., died on active service in July. He was born on May 18, 1912, and was educated at Aberdeen Grammar School and at the University of Aberdeen, where he graduated M.B., Ch.B. in 1936. He held house posts at Walsall and Kettering hospitals and was in general practice for eighteen months before being appointed A.R.P. assistant medical officer for Southgate. He entered the R.A.M.C.(T.A.) in Aug., 1937, was promoted capt. a year later, and was called up immediately war broke out. He was posted to the Middle East early in 1940 and served in Palestine, Iraq, and Syria. In April, 1941, he was mentioned in dispatches for distinguished services. He leaves a widow. He was a member of the B.M.A.

Temp. Major **Thomas Gerald Martin**, R.A.M.C., is included as "died" in an Army Council Casualty List published on Sept. 25. He was born on Aug. 24, 1906, and graduated M.B., B.Ch., B.A.O. (with honours) at the National University of Ireland, and gained the Blayney prize and the Pearson gold medal in 1931. He also took the D.P.H.Lond. He had held house posts at Sheffield Royal Hospital, and in 1937 settled in practice in London. He entered the R.A.M.C. in Nov., 1939, and was promoted capt. a year later.

An India Office Casualty List announces the death of Lieut.-Col. **Bishambhar Sahai**, I.M.S. He was born on Oct. 17, 1888, and was educated at the University of Calcutta and at Charing Cross Hospital, qualifying M.R.C.S., L.R.C.P. in 1916. He immediately took a temp. commission in the I.M.S., and in 1920 received a permanent commission, being ranked as capt. from 1919. He became lieut.-col. in 1931. He served in France and Flanders during the war of 1914-18, receiving the medals.

Prisoners of War.—Major J. A. G. Carmichael, R.A.M.C., War Subs. Capt. H. D. Fleming, R.A.M.C., War Subs. Capt. C. D. Holdstock, R.A.M.C., Capt. W. O. James, R.A.M.C., War Subs. Capt. J. C. Mustardé, R.A.M.C., Capt. P. Turner, R.A.M.C.

Missing.—Capt. C. V. Lewis, R.A.M.C.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the seasonal rise in the incidence of infectious diseases which is expected in early autumn appears to have begun. A rise, in some cases substantial, occurred in the number of notifications of every disease excepting typhoid fever, which fell by 17 cases.

There was a small rise, 23 cases, in the incidence of diphtheria, the notifications of which are now 36% larger than four weeks ago. No marked contrasts exist between the area totals of last week and this week.

The notifications of scarlet fever have also shown a continuous rise during the past four weeks and are 264 more than last week. The rise was fairly general throughout the country, the record increase being 75 in Yorks West Riding.

The notifications of whooping-cough were 76 more than last week. The trend of the incidence within the counties fluctuates from week to week, the largest variations during the week reviewed being a rise of 26 in Yorks West Riding and a fall of 23 in Middlesex.

The incidence of measles, which had been continuously declining for eleven weeks, during which the weekly totals fell from 7,581 to 2,644, rose by 354 cases. The additional cases came from the North Country. The increases were Yorks West Riding 116, Lancashire 60, Cheshire 58, Cumberland 49, Northumberland 42. In the southern part of the country the incidence continued to decline, except in London and Middlesex, where 38 and 30 cases more than last week were recorded.

Although the notifications of dysentery rose by 38 there was no new outbreak of any size. Small numbers of cases occurred more frequently than usual and ten more counties reported cases than during the preceding week. The outbreak in Oxfordshire fell from 41 to 14 (Oxford C.B. 5, Bullingdon R.D. 9), while in Norfolk there was a rise from 16 to 36 (Norwich C.B. 13, Swaffham R.D. 18, St. Faiths and Aylesham R.D. 5). The largest of the other county totals were Lancashire 20, London 16, Surrey 10.

In *Scotland* there was little change during the week. The only noteworthy variation was an increase of 33 cases in the notifications of scarlet fever. The chief centres of infection of this disease were Glasgow 76, and Edinburgh 68.

In *Eire* there was a relatively large increase, from 15 to 31 cases, in the incidence of poliomyelitis. The cases were widely distributed, and involved fifteen districts. The largest centre of infection was in the county of Louth (Drogheda U.D. 5 and Louth R.D. 5); 5 cases were also reported in Dublin.

Quarterly Return for Eire

The report of the Registrar-General for the second quarter of 1942 shows that the general position was better than in the corresponding quarter of 1941.

The birth rate was 24.5 per 1,000, being 4.5 above the rate for the June quarter of 1941 and the largest recorded in any quarter during recent years. The infant mortality was 62 per 1,000 registered births. This rate was 9 below that of the second quarter of 1941 and 5 below the average of the June quarter of 1937-41.

The general death rate was 14.6 per 1,000. Although this was 0.5 below the rate for the corresponding quarter of 1941, it was slightly higher, 0.2, than the average for 1937-41. Deaths from puerperal causes were 2.2 per 1,000 births, an increase of 0.2 on the value for the second quarter of 1941 but considerably lower than the rates for the corresponding quarters of 1937-40, when the rate varied from 2.3 to 4.3. The death rate from tuberculosis was 1.7 per 1,000 compared with 1.3 in the previous year, and was the largest rate recorded in a June quarter during recent years. The increase was mainly due to pulmonary tuberculosis with 1,011 deaths compared with 738 in the second quarter of 1941.

Returns for the Week Ending September 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,963, whooping-cough 938, diphtheria 807, measles 3,356, acute pneumonia 459, cerebrospinal fever 70, acute poliomyelitis 32, dysentery 237, paratyphoid 13, typhoid 9.

Helen Wyandt and her colleagues (*Arch. intern. Med.*, 1941, **68**, 1043) report 86 new cases of elliptic erythrocytes in three large families of German extraction. In this series elliptic red cells were found in one member of each of two pairs of twins, in the other member of which the cells were round. In one family both the mother and the father had large numbers of elliptic red cells. The authors state that their investigation lends support to the opinion that the anomaly has no definite relation to disease.

No. 37

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 19.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

At a meeting of the Royal Sanitary Institute to be held at 90, Buckingham Palace Road, S.W., on Wednesday, Oct. 21, at 2.30 p.m., a discussion on "Scabies" will be opened by Dr. Henry MacCormac, Dr. Thomas Standring, and Major C. G. Johnson, R.A.M.C.

A meeting of the Therapy Section of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, Oct. 17, at 10.30 a.m., when there will be a discussion on beam direction in radiotherapy.

A Christie pension of £89 per annum will in November be awarded to a necessitous medical man fully 55 years of age, who has been registered for 5 years, and who is in need of help. Forms of application may be had from the Secretary's Office, Epsom College, Surrey, and must be completed and returned by Oct. 26.

The address of the Drugs Branch, Home Office, is now Cornwall House, Stamford Street, London, S.E.1. Telephone number Waterloo 8070.

After a trial lasting eight days at the Central Criminal Court Dr. Francis Percival de Caux of Green Street, W., and with a country house at Marden, Kent, was found guilty on eight of nine counts charging him with performing illegal operations to procure the miscarriage of women. The jury were at first unable to agree upon a verdict, but after a second retirement they recorded their verdict and also found Dr. de Caux guilty of conspiring with another woman to attempt to procure her miscarriage. Supt. Smeed of the Kent County Police said that 75 women had been seen by the police in the course of their inquiries, and 35 admitted they had undergone an operation; 47 women had been treated and the fees paid amounted to £2,698. Mr. Justice Hallett, passing sentence of five years' penal servitude, and two years' imprisonment on the second charge, the two sentences to run concurrently, said, "You must have known all through the penalties that would follow such a practice, and you did your best to cover up your activities."

The Medical Research Council has received a bequest of the residuary estate of the late Mrs. Emily Inston of Sandbach, Cheshire, to be applied to the furtherance of research work on arthritis.

Dr. H. D. Clementi-Smith and Dr. M. H. Watney have been elected wardens of the Mercers' Company.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary

QUERIES AND ANSWERS

Post-mortem Lividity

Dr W. W. MACKINLAY writes: In my textbook (Glaister) the time of earliest appearance of post-mortem lividity is stated to be 8 to 14 hours and in exceptional cases 5 hours. Recently this phenomenon was observed when I examined a body at 1 p.m. where death undoubtedly took place after 10 a.m.; the time elapsing being thus certainly less than 3 hours. I should be glad to have the comments of those of extensive medico-legal experience. I may say that the case was a cardiac one—probably aortic. This, of course, may have had considerable influence on time of appearance.

Itching of Limbs

Dr. F. M. PURCELL writes in reply to Dr. W. A. Milligan (Aug. 5, p. 208): During recent months I have been treating a bed-ridden man, aged 72, suffering from chronic heart disease and paresis of the limbs. He has been under medical treatment for many years, and during the last year or so has suffered from severe generalized pruritus. Already he had tried various antipruritics without relief; I fared no better than my predecessors until July, when, in curiosity, I prescribed 1,000 B units of oestrone twice daily by mouth. Prompt relief followed, and has been maintained on two three-weeks courses. The itching had been persistent and intractable, the skin scratched and pigmented; the poor old wife was in great distress as the husband's sleep was so upset. He has not complained of the itching again since July. Last month I prescribed 1,000 B units for another elderly man, who was also complaining of chronic generalized itching. Each week he has admitted improvement under this treatment, not complete relief, but considerable: he is not an enthusiastic patient. Neither of these patients was diabetic.

LETTERS, NOTES, ETC.

Fly Pest

Dr. J. B. WRATHALL ROWE (Harrow) writes: I have noticed a considerable increase in the numbers of the common house and other flies during the past summer compared with previous years, and attribute this to the greater use of garbage bins which are now dotted about the streets for the reception of pig food. While realizing the necessity for collecting pig food in this way, I feel that attention should be drawn to the need for destroying as many flies as possible next spring and summer if we are not to be faced with outbreaks of fly-borne diseases such as summer diarrhoea. Steps should be taken now to begin the manufacture of fly-traps and other means of killing them. The ordinary fly "swatter" is practically unobtainable and in any case is an inefficient and messy instrument. I have been experimenting lately with a de Vilbiss atomizer, and find that if ordinary commercial paraffin is used in it and the spray directed on to the fly the latter rolls over and dies with astonishing rapidity. The corpses can then be collected and burnt. I believe the cause of death is asphyxia resulting from blockage of the air ducts by the paraffin. Incidentally, ordinary paraffin is very much cheaper than the proprietary insecticides on the market—about 4d. a quart compared with 2s. 6d. a pint—and is just as efficacious. It does not stain and evaporates in time from walls and ceilings. It should not, of course, be used in proximity to food or open flames.

Bureaucracy in Rubber Gloves

Mr. A. J. BLAXLAND (Norwich) writes: On July 22 I applied to the Regional Office of the Ministry of Health for a supplementary ration of rubber operating gloves. I stated that my practice was entirely a surgical one and gave an estimate of my average yearly consumption. After an interval of six weeks I received a letter asking what my basic ration had been. I replied, by return of post, that it had been the usual three pairs of gloves, and I requested that I might be allowed a supplementary ration as soon as possible, as my reserve stock was nearly exhausted. I received a certificate for extra gloves this morning—i.e., nearly ten weeks after my application. I grant that this may be considered a somewhat trivial affair, but it seems to me to be typical of the dilatory methods that one may expect of the bureaucratic control in a Government Department. It would not be tolerated in any ordinary business concern; and it is one illustrative portent to our profession of what to expect in a State Medical Service.

Bleeding Tooth Sockets

Dr. S. JUNG (Heworth, York) writes with reference to Dr. J. T. Maclachlan's note (Sept. 19, p. 356): May I draw attention to a simple method to stop bleeding tooth sockets. Once when I failed to stop the persistent welling-up of blood into the mouth by use of silver nitrate, and attempts to plug the socket of the bleeding tooth with small strips of gauze also proved unsuccessful, I inserted a cork of a small bottle into the socket. I had sterilized the cork by boiling it in water for ten minutes, and I removed it after 24 hours. Since then I have used this method 3 or 4 times, always with success.

"The Pleuro-subpleural Zone"

Dr. J. SKLADAL writes from 26, Trinity Street, Cambridge: I was rather surprised by the review of my monograph in the *British Medical Journal* of Sept. 5, made under the heading "An Auscultatory Method." Regretting very much indeed that the reviewer did not attend the meetings of the Royal Society of Medicine and of the Physiological Society in November last year, at which both occasions I demonstrated the method of sudden expiration and one patient with cortico-pleural lesions, as also the mechanism of the reduplicate sound on the physical model, I would stress my readiness and, as I think, my duty, too, to endeavour to convince everyone who doubts about the findings and conclusions given in my monograph.

BLOOD TRANSFUSION IN THE U.S.S.R.

BY

Prof. A. BAGDASAROV

Director of the Central Blood Transfusion Institute, Moscow

Blood transfusion cannot to-day be regarded merely as a substitute method of medical treatment. It should really be designated by the term "haemotherapy"—i.e., treatment with blood—as, in addition to the infusion of fresh blood, elements which stimulate and alter its reactions, mainly in a beneficial direction, are likewise introduced into the organism. This is usually followed by restoration of the functions of various diseased organs.

Blood is distinguished from all the tissues and organs by virtue of its extraordinarily wide range of functions. Besides its own life, it reflects in itself that of all the organs and systems. Not only does the blood distribute the oxygen it obtains from the lungs but it also serves as a universal medium in metabolism and carries within itself the products of nutrition and disassimilation. The chemical stimulators of vital processes, fragments of hormones, as well as catalysers—ferments and protective substances—are all concentrated in the blood. These factors are no doubt of fundamental significance in rendering blood transfusion one of the most effective measures known in medical practice.

Its Wide Application

The wide application of blood transfusion in the U.S.S.R. was preceded by research work by a number of Soviet scientists (among them, Academician A. A. Bogomoletz and Academician S. I. Spasokukotsky), who sought to establish the mechanical basis of the effect of blood transfusion and to determine indications and contraindications in applying this means of treatment.

The application of blood transfusion has greatly developed since 1926, when a special institution was founded in Moscow—the Central Institute for Blood Transfusion (I.P.K.)—under the auspices of the People's Commissariat for Health of the U.S.S.R. (Narkomzdrav); and parallel with this development there proceeded research work which resulted in the scientific establishment of several points touching upon this method. Blood transfusion is to-day performed in all medical institutions throughout the U.S.S.R., and the number of such transfusions has grown rapidly year by year. Whereas in 1935 the officially registered cases of blood transfusion numbered 22,000, by 1940 this figure had mounted to 200,000, excluding transfusions given on the Finnish front in that year.

With us, blood transfusion always had a definite ultimate aim—the utmost possible use of this prepotent medical treatment in wartime. And this urged us to solve the problem of organization, to train all physicians in the giving of blood transfusions, and to set up special institutes and stations—future blood-purveying depots—in all regional centres and large towns. This work has made great progress during recent years. Whereas in 1932 there were only about 80 such institutions in the U.S.S.R., by 1941 their number had reached 1,500; and, of course, there has been a corresponding growth in the number of donors. Soviet scientists, too, demonstrated their theoretical and practical achievements in the sphere of blood transfusion at the 1935 and 1937 International Congresses on Blood Transfusion.

Blood Conservation

At the outset blood transfusion in general practice was resorted to mainly as an emergency measure. There then arose the task of finding preservative agents which would allow blood to be conserved and retain its biological qualities for considerable periods of time. The solution of this problem facilitated the urgent transfusion of blood in times of peace, and particularly so in wartime. Nowadays we consider it an ordinary matter to ship conserved blood by aeroplane over distances of hundreds and even thousands of miles into the most distant corners of the tundra and taiga, and into the steppes and deserts of the south-east regions of the Soviet Union. No small number of human lives have already been saved, thanks to the speedy transportation of conserved blood by aeroplane to the front lines from far inland. And in this connexion the utility of various isothermic containers for shipping blood over long distances is worthy of special attention.

Hundreds of thousands of transfusions of conserved donors' blood have been made in the U.S.S.R., and this source ranks first among all sources of blood for transfusion. Only a few years ago conserved blood could be stored for not longer than 15 days, and under conditions of transportation, when the blood was subject to being shaken and jolted, this was reduced to 10 days. In recent years, however, great success has been attained in lengthening the period over which conserved blood can be kept: the addition of a small quantity of glucose to the sodium citrate solution substantially improves the storage properties. Blood conserved with a glucose-citrate solution can be successfully kept in a condition suitable for transfusion for 25 days, and for 20 days when transported. Experience in the war has shown transport by aeroplane to be the main, and the most preferable, method of shipping conserved blood to the front, even from distances of thousands of miles.

Soviet physicians have paid particular attention to designing appliances for taking blood and for the transfusion, storage, and shipping of conserved blood. Practice has shown that standard rectangular jars which fit into an isothermic container best answer the purpose of uniting in one vessel both the taking and the transfusion of blood; they are also very convenient for transport. These jars, which are produced on a mass scale, are placed inside the insulated containers, in which the blood keeps irrespective of external heat or cold. The ampoule type of appliance for blood transfusion is also eminently suited to the purpose, being easily portable and simple in use.

Utilization of the blood of "universal" donors acquires great significance under wartime conditions. Soviet scientists have accomplished a great deal of work in solving this problem. Without any complications whatever, massive doses of group O (IV) blood are now transfused to recipients of other groups who have lost a great deal of blood. And this is done actually at the front. Here the blood of universal donors is of particular value to active service medical stations, for there is often no opportunity for blood grouping.

Another matter of much importance for ensuring supplies of conserved blood at the front, and for its transfusion, is the efficient organization of stores of blood and their shipment. Our main supply base for conserved blood is the network of blood transfusion institutes and stations of the Narkomzdrav which have been established all over the country. When war broke out, many of these institutes and stations swiftly and efficiently readapted their work and became main bases for the mass purveyance of conserved donors' blood for dispatch to the front and to hospitals in the rear. During twelve months of war literally hundreds of tons of blood have been thus applied to wounded men in all stages of evacuation, and with truly tremendous success.

Narkomzdrav regularly sends out groups of experienced specialists—scientific collaborators from the institutes and stations—who give practical assistance in ensuring the adequate supply of conserved blood at the front. Thus, thanks to timely blood transfusion, we can indeed say that hundreds of thousands of human lives have been saved.

The Plasma Method

The most diverse methods of haemotherapy have been extensively used—the drip method of blood transfusion, the transfusion of plasma and serum, immunotransfusion, the injection of small doses of blood of incompatible groups, and heterohaemotherapy. Among these the plasma method has a particularly wide scope in present wartime conditions. It is known that blood plasma is the main substratum of metabolism; and its most striking feature is that, despite the constant inflow of matter and energy, its composition remains unaltered. Soviet scientists are in complete accord with the conclusions of British and American scientists that, as a medium impregnated with plastic substances and containing a large quantity of ferments exerting a haemostatic action on the organism, as well as a medium in which viscosity and osmotic pressure are almost at the same level as in whole blood, plasma beyond a doubt possesses unqualified advantages as a blood substitute.

With the object of establishing the most favourable conditions for preserving plasma over long periods we have had recourse to freezing it. As did M. Struma and S. M'Graw in their investigations, the Central Institute for Blood Transfusion has found that when plasma is frozen and afterwards quickly thawed at a temperature of 37° C.—immediately preceding transfusion or a short while before—it preserves intact such labile elements as prothrombin, fibrinogen, and complement. Recently we have introduced into practice desiccated plasma and serum preparations. Under front-line conditions plasma finds wide scope as a highly active haemostatic agent in cases of protracted loss of blood in which the transfusion of massive doses of blood is contraindicated. As a substitute for blood, plasma is employed in cases of shock accompanied by a moderate blood loss, when the organism still retains an adequate reserve of erythrocytes. In cases of burns we have found plasma of great service. When introduced in large volume, following heavy loss of blood, it usually has a most striking detoxicating effect. We employ various balanced physiological solutions for preserving the erythrocyte mass remaining after the plasma has been separated. We have recently been using the following solution: $MgSO_4$, 0.04 gr.; KCl, 0.2 gr.; NaCl, 8.5 gr. per litre of double-distilled water. It has been termed the modified I.P.K. fluid.[*] This fluid is mixed with the erythrocyte mass in different ratios. After the plasma has been separated from them and replaced with the modified I.P.K. fluid, the conserved blood erythrocytes are preserved in an external temperature of 4° to 6° C. Under these conditions they show no marked change up to 12 days, including the day the blood was taken from the donor. The transfusion of conserved blood erythrocytes containing this plasma substitute was found most effective in those cases of anaemia in which the aim of medical treatment is preferably to obtain a substitutive effect—that is, cases of much loss of blood, regenerative forms of post-haemorrhagic anaemia, etc. Naturally, the erythrocyte mass method is of service mainly in hospitals situated not far from the institute or station preparing these erythrocytes.

Plasma Substitutes.—The wide application of blood transfusion in the U.S.S.R. and the generous manner in which donors give blood for the needs of the Army and civil medical institutions have not relegated the question of blood substitutes, or, rather, plasma substitutes, that can be employed in all cases in which the main object is that of augmenting the volume of circulating blood. From our point of view, any physiological solution containing only salt ingredients, without colloids to maintain the viscosity and osmotic pressure of the solution on a level approaching that of plasma, is useless as such a substitute. Balanced solutions containing a small volume of blood or plasma have recently been finding a practical use as isotonic fluids with a natural colloid. Other solutions also serving this end are those in which the colloidal properties are ensured by adding casein that has been specially processed, with the object of eliminating the antigenic properties inherent in this preparation. The complicated circumstances existing in the front line sometimes preclude the possibility of utilizing conserved blood within its period of serviceability, and these are the conditions under which plasma, as well as synthesized substitutes for the latter, is of chief use. From a fairly wide experience we may draw the conclusion that in cases of acute loss of blood and shock, when infusion of plasma substitutes is carried out in conjunction with haemotherapy, a favourable influence on the condition of the patients' haemodynamics is usually obtained by the use of small doses of blood or plasma

Side by side with colloidal substitutes for plasma we have recently introduced on a wide scale so-called physiological balanced solutions containing alcohol and glucose. These solutions, which mainly reinforce the vital processes, are administered in cases in which the wounded patient suffers from disturbed haemodynamics not associated with heavy blood loss, and also in septic cases.

It is no matter for surprise that since the outbreak of war a tremendous number of Soviet patriots have streamed into the numerous blood transfusion institutes and stations. From early morning till late at night these institutions seethe with activity. New donors undergo medical examination, their blood groups are checked, blood is taken and conserved, and jars and ampoules are packed for urgent dispatch to the front And these donors are not only the donors—so to say, "cadre" donors—who used to give blood for transfusion before the war. They largely consist of the huge number of those who declared their desire to give blood for transfusion to the wounded when necessity arose. This great army is held in reserve, and at the very first call they flock to the transfusion centres to give their blood. And this reserve army has been augmented to-day by a great number of people in all walks of life. Even the briefest of informative talks on the important part which blood transfusion and the donor play in the Soviet army medical services suffices to bring to the institutes and stations groups of workers, students, militiamen, housewives, and the wives of those on active service, expressly to join the ranks of donors.

COMMENTS ON AN EPIDEMIC OF HEPATITIS

BY

PHILIP EVANS, M.D., M.Sc., M.R.C.P.

Assistant Physician for Children, King's College Hospital

The hospital in which the epidemic occurred was formed in Sept., 1939, and has catered for up to 120 children at a time, as well as for a variable number of adults. The children have been nursed mainly by children's nurses in training, and these young women have been chiefly affected.

History of the Outbreak

In March, 1940, a nurse became jaundiced (Table I), and a second case occurred 35 days later. Shortly afterwards 2 nurses were transferred from another hospital, where the infection was rife, and they soon developed the illness. In August another nurse was affected, and in October another. Thus in 7 months 4 nurses probably acquired the disease in the hospital, and this epidemic period was followed by an outbreak in one ward affecting in a month 5 children and 5 nurses who worked in that ward, while 2 nurses and a ward-maid were probably infected in the nurses' sick-rooms. The outbreak later declined, but during the final 17 months' observation a further 8 children and 30 nurses became jaundiced. Ten children who had acquired the disease elsewhere were also admitted during this time.

---

[*] I.P.K.—initial letters of the Russian for "Blood Transfusion Institute."

Table I shows the ramifications of the epidemic. From its study certain features may be picked out for comment.

64	Child	C4	C4	C4	11/5/42	18/5/42	
65	Nurse	C4	Away	Away	4/6/42		

C1, C2, C3, C4, and C5 are children's wards. M. is the maternity ward. A1 and A6 are adult medical wards. N.S.R. means nurses' sick-rooms (attached to C3). "Away" means outside the hospital.

The endemic stage, in which single cases appeared at intervals of 1, 2, and 3 months, shows that infection was smouldering in the hospital for some time before conditions were ripe for an epidemic. It suggests, too, that the incubation period varies widely and may be longer than 3 months, that there are carriers, or that subclinical infection may occur.

Subclinical infection here means infection without jaundice, but not necessarily without symptoms. No proof of the existence of such infection was found, but several observations suggest that it does exist. No direct source of the outbreak in ward C4 was discovered, but a nurse in that ward had an attack of frequent vomiting, without pyrexia, diarrhoea, or jaundice, on Dec. 1 and 2. She was admitted to a nurses' sick-room (attached to C3 ward). Jaundice followed in patients in C4 from Dec. 22 onwards, and in the sick-room attendants from Jan. 9.

Late in 1941 another nurse was in C4 when a boy developed jaundice for one day (Oct. 29). The nurse had an attack of severe vomiting for which she was "warded" from Nov. 21 to 28; she was nursed by patient No. 56, who was not in contact with any known patient with jaundice but who developed the disease on Dec. 15.

Young children usually have mild attacks, often consisting only of a pale stool or two, faint jaundice, bile in the urine for a day or so, and a rise of temperature to 99°–100°. It is easy to imagine yet milder attacks in which jaundice is not noticeable. For instance, a boy aged 2 in ward C5 seemed out of sorts and lost his appetite for one day. He passed one pale stool, but had no jaundice of conjunctiva or urine, and the occurrence would have attracted little notice if 4 children and a nurse had not developed hepatitis in that ward during the preceding 11 days. No one who reads Newman's (1942) persuasive paper is likely to doubt the existence of abortive cases. Cullinan (1939) has described a patient seen by A. W. Franklin who had biliuria in the morning but not in the afternoon. Case 54 had only a trace of jaundice of the conjunctiva, and had biliuria for one day.

Incidence of Hepatitis

That age affects the development of hepatitis even in children is a clinical impression: children from 1 to 4 years old seem to have brief mild attacks with slight jaundice, and often negligible prodromata. Table II bears out the contention that young children are relatively insusceptible. Babies are almost immune, though instances have been recorded (Cockayne, 1912-13). It is notable, too, that junior nurses were more likely to acquire the infection than senior: many of the latter had already had attacks. The regulations which permit, and thus ensure, that girls training as sick children's nurses shall be younger than those doing general training are partly responsible for the prevalence of infectious fevers in children's hospitals.

TABLE II.—*Age of Children admitted to Hospital, and Number getting Jaundice, between April 25, 1940, and May 31, 1942*

Age in Years	No. of Admissions		No. with Jaundice	
0	243	921	0	2
1	181		1	
2	150		0	
3	158		0	
4	189		1	
5	152	980	2	11
6	133		1	
7	118		3	
8	93		1	
9	118		0	
10	98		1	
11	94		1	
12	76		2	
13	76		0	
14	22		0	

Studies of the *seasonal incidence* (cf. Wallgren, 1930) show infectious hepatitis to be chiefly a disease of autumn and winter, though there are many exceptions. In the present outbreak the epidemic wave developed in the winter and spring of 1940-1, but there was no second wave the following winter (Table III). The ventilation of the blacked-out wards at night

was better in the second than in the first winter, but this is probably irrelevant, for day and night nurses were affected in proportion to their numbers.

The Incubation Period

The incubation period has been variously estimated. Glover and Wilson (1931) and Glover (1939) considered that the abrupt character of the outbreak they studied suggested a short incubation period, probably of 3 to 4 days. The majority of recent authors favour a longer period, and the conclusions of Glover and Wilson have been criticized by Pickles (1939b). Booth (1928) put it at 20 to 40 days, Pickles (1939a) at 23 to 35 days in three outbreaks. Most calculations have been based on case-to-case intervals, and there are few records of single exposures. Booth (1928) records one which indicates an incubation period of 31 days. Newman (1942) had instances of 29, 30, and 31 days. In one of Bashford's (1934) adult patients the period was apparently only 8 to 10 days. Wallgren (1930) observed hepatitis 15, 21, 20 to 22, 22 to 25, 25 to 28, 23 to 29, 8 to 15, and 31 to 40 days after exposure. Pickles (1939b) has good examples of 27, 27, 28, 28, 29, 31, and 34 days.

A few observations were made in the present outbreak. Case 24 was "warded" on March 17 and became jaundiced 8 days later. Children in her ward developed the disease 40, 45, 48, and 50 days after the last contact with her, and another nurse in the ward developed hepatitis after 47 days. These are long periods, but no trace of an intermediate infection could be found, and to postulate one would merely substitute two unusually short periods for one unusually long one. Case 48 was exposed to infection 53 to 40 days before becoming ill, and not at any other time so far as was known. Case 57 was ill and was nursed by Case 56 (who developed hepatitis on Dec. 15) from Dec. 8 to 14, and developed jaundice on Jan. 18, an interval of 35 to 41 days. In Cases 2, 46, and 47 incubation took more than 34, 29, and 35 days respectively; in Case 53 less than 35 days; in Case 38 it was probably exactly 38 days.

It seems that infection usually takes about a month, but that longer or shorter periods are possible. The size of the infecting dose may well be important, as in enteric fever. There may also be differences between strains of the unidentified hepatotoxic agent; perhaps different routes of infection may also produce different incubation periods. Propert (1938) observed that jaundice developed 78 to 83 days after the injection of human serum which was probably contaminated with a virus causing hepatitis, and two contacts of the original patients developed jaundice two months later. This batch of serum produced cases elsewhere (MacNalty, 1938; Findlay, 1940). According to Findlay (1940), yellow fever vaccine, similarly contaminated, produced jaundice 2 to 3 months after injection.

Duration and Degree of Infectivity

The *duration of infectivity* is thought by Pickles (1939a, 1939b) to be short, chiefly because not all the susceptible members in a family epidemic develop jaundice in one batch after exposure, but instead become ill in succession at intervals of about a month. This curious sequence has been equally plausibly explained by Newman (1942), who postulates a phasic or intermittent susceptibility to the infection. Pickles has actually noted transmission 8 days before the development of symptoms, and on the fifth and seventh days of the disease. Bates (1936) suggested that infection could still be transmitted a month after jaundice appeared; but this is not a common experience, and other explanations of his observation are possible. The epidemic described here did not provide information about the limits of the infectious period, although it was clear that infection might be transmitted some time before jaundice showed—e.g., Case 24 infected 5 people on or before March 17, when she became ill, although she was not jaundiced until March 25.

The *degree of infectivity* is difficult to estimate, but a rough idea may be obtained from Table IV, in which the number of times a patient or a nurse developed an acute infectious fever in an apparently uninfected ward is compared with the number of times a secondary case followed the occurrence. It will be seen that in this computation (which does not include children admitted to hospital after jaundice had appeared or abortive cases) infectious jaundice occupies a middle position between the more and the less infectious fevers.

TABLE IV.—*Number of Times a Secondary Case followed the Development of an Infectious Disease in Four Similar Children's Wards*

Disease	No. of Times Infection introduced (A)	No. of Times a Secondary Case followed (B)	Index of Infectivity (B/A)
Chicken-pox ..	10	9	0·9
German measles ..	6	5	0·8
Mumps	5	3	0·6
Infectious jaundice ..	11	6	0 6
Whooping-cough ..	12	5	0·4
Scarlet fever ..	11	1	0·1

Pharyngitis without rash following scarlet fever and abortive hepatitis are not included.

Transmission of Infection

The mode of transmission of infection in this epidemic, as in most, appeared to be aerial, and perhaps also by contagion. The frequency with which nurses became infected by nursing patients is striking when compared with the rarity with which patients in bed infected other patients, and suggests the possibility of the acquisition of the virus from faeces or urine This is certainly not the usual route, for patients may infect one another by close proximity in out-patient waiting-rooms (Graham, 1938; Cullinan, 1939; Barber, 1937). A head master infected some pupils by merely walking through the rooms they were in (Newman, 1942); a rent collector visited infected houses and was himself stricken (Nicol, 1942). In one curious case (No. 38 in Table I) a sister spent a day in the next room to a nurse who had just developed jaundice, and came down with it herself 38 days later. There was no direct communication between the rooms, but the two doors opened side by side into a common corridor, and the two patients were nursed by the same staff. Apparently contact need not be very close, although it undoubtedly usually is. Wider spacing in a hospital waiting-room has been followed by the ending of an outbreak (Barber, 1937).

Usually a direct communication can be traced from case to case, while at times an abortive case seems to be the cause I doubt if healthy carriers played much (or any) part in this epidemic, although their existence has been suggested by Cockayne (1912-13) and Newman (1942).

Some Further Points

Relapse is uncommon, but has been recorded (Cockayne, 1912-13; Bates, 1936; Newman, 1942): I have seen it once in a man aged 53. *Second attacks* are rare, but are mentioned by Findlay, Dunlop, and Brown (1931) and Newman (1942) *Convalescence* is long. Many non-medical people do not think "the yellow jaundice" is catching, nor do they realize that it may make a patient feel ill and exhausted for weeks. It is often treated as an "ambulant illness," but it is in fact an important cause of loss of health: few nurses at this hospital were well enough to work in as short a time as a month. Blood sedimentation rates may remain elevated for several weeks (see Chart).

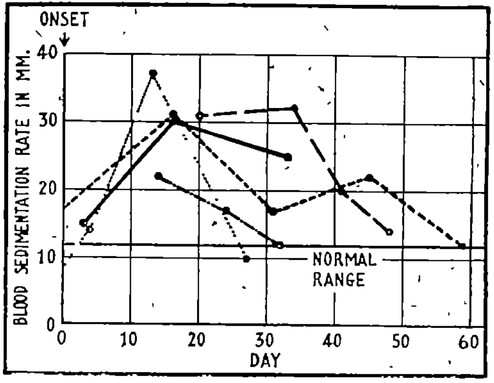

Chart showing the blood sedimentation rate (Payne's method) in 5 children who had mild attacks.

Finally, the role of a children's hospital as a *reservoir of infection* is obvious. There is a long incubation period, and many nurses happened to be on holiday when they became ill, and thus carried infection into parts of Berkshire, Hampshire, Kent, Lancashire, Middlesex, Oxfordshire, Staffordshire, and Sussex. There seems no reason why the thread of infection should die out of the hospital while it exists in its present form, for its population is continually being refreshed by the influx of susceptible children and young nurses. If this should not be enough, another outbreak could be started by the admission of a patient incubating the disease—a fairly common event.

Summary

Infectious hepatitis became endemic in a hospital early in 1940, and in the following winter an epidemic started. It gradually subsided in the next year and a half, but the frequent introduction of young nurses and children into the community is likely to maintain the infection and form a reservoir from which the disease can be distributed to other places.

Infection is usually transmitted from case to case, but abortive cases are probably important links in the chain of infection.

Young children and senior nurses are less susceptible than older children and junior nurses.

The incubation period is usually about a month, but shorter and considerably longer periods are possible. The duration of infectivity is uncertain. Hepatitis is easily transmitted, but is probably less infectious than varicella or rubella.

The disease often produces several weeks of invalidism. The blood sedimentation rate may remain elevated for some weeks after a mild attack.

IN-PATIENT TREATMENT OF CIVILIAN NEUROTIC CASUALTIES

REPORT ON 100 CASES TREATED IN AN E.M.S. NEUROSIS CENTRE

BY

W. S. MACLAY, M.D., M.R.C.P., D.P.M.
Medical Superintendent, Mill Hill Emergency Hospital

AND

J. WHITBY, M.D., M.R.C.P., D.P.M.
Psychiatrist at Mill Hill Emergency Hospital

The Emergency Medical Service is responsible for the care of civilian casualties. As a result of enemy action, particularly after the severe air raids in the autumn of 1940, some of the neurotic cases continued for a prolonged period to be unfit for work, and it was decided that specialized investigation was required to determine whether their condition was in fact due to "war injury" and whether they could be benefited by in-patient treatment at a neurosis hospital. Cases of long standing were therefore seen by a psychiatrist, and those suitable were offered in-patient treatment.

This paper is based on a study of the first hundred patients who passed through the hospital between July, 1941, when the scheme came into operation, and January, 1942. The total number referred was very little more, and as this hospital serves a large area, including London, there would appear to have been but few neurotic casualties in the country at that time. The paper is not intended to be a statistical one, but to point to factors of interest in the aetiology of the illness, and to the results of treatment.

The material investigated consisted of 70 men (of whom 20 came from Services such as Fire, Police, or Merchant Navy, the remainder being civilians) and 30 women, none of whom were in these Services. Their average age was 45 years, which is significantly higher than the average age of the usual patients attending practitioners at this period, and indicates that the special stresses fell more heavily on the older age groups. All had been closely exposed to bombing, which constituted the precipitating factor and which was followed by incapacity for work. They may therefore be considered in chronological periods before and after this incident.

Before the Incident

Family history may be disregarded, as, although information concerning neurosis or psychosis in close relatives was inquired for, a positive history was rarely obtained. Significant physical illness occurred in 11 instances. Among these were physical disorders such as cerebral arteriosclerosis and Parkinsonism now masquerading as neurotic illnesses. Other physical disorders, although contributing to the total picture, did not affect the prognosis of the neurosis. Definite neurotic illness had occurred in 13 patients and psychosis in 3. These figures are high for the general population but low for neurosis cases in pre-war practice, and would indicate that many, but not all, of the illnesses arose in people who do not easily break down. The diagnosis of the previous illness was not necessarily the same as the present one, hysteria being the only condition that recurred relatively often.

Personality characteristics of a kind which are usually regarded as predisposing to illness, such as "timid," "nervous," "worrying," "irritable," or "obsessional," and which were sufficiently marked to be apparent, occurred in 24. They coloured the content and contributed to the total picture of the illness, but they were not correlated with the diagnosis, and bore no relation to the outcome of the illness. Although it may be argued that predisposition could have been found in 100% if enough trouble had been taken, the fact remains that by ordinary standards a large proportion of these patients had had a good previous personality. This is one reason why the results of treatment were good. These cases are not comparable to the compensation neuroses of peacetime or to the soldiers who are unable to adapt to Army training; rather should they be compared to soldiers of good personality who broke down after such exceptional stress as Dunkirk and who tended to make a quick recovery in hospital. That a large number had stable personalities is confirmed by the fact that 90% of the men had steady work records, unlike the work histories so often obtained among peacetime neurotics.

In the period immediately preceding the incident 30 cases had been subjected to prolonged stress, beyond that of the average civilian, by virtue of their special occupations, including those in the Fire, Police, and A.R.P. services or in the Merchant Navy. Of these, 19 had begun to show symptoms but had not been off work. Nevertheless in these cases the results of treatment as regards symptoms were no different from the others.

The Precipitating Incident

The comparison with the Dunkirk cases is apt in that our patients were not those who broke down through a bomb merely dropping somewhere in the neighbourhood. On the contrary, 86 as a result of bombing had endured severe mental stress, such as loss of husband, wife, or children, loss of home or business, or being buried for hours. The severity of the incident is borne out by the fact that 50 sustained physical injury also, excluding minor bruising. It is interesting to note that among soldiers in the last war neurotic illness rarely coexisted with physical injury. Presumably anxiety in a soldier is relieved by a wound which will remove him from the battle area; but this does not happen to the bombed civilian, and other factors become more important.

Another common finding in these patients was that the majority had previously heard bombs exploding in the vicinity without developing any more anxiety than is usual, but once they were actually blown up they tended to become afraid of a repetition of the experience. Feeling a bomb is quite different from hearing one.

After the Incident

It is well known that most of those who got acutely anxious, hysterical, or panic-stricken recovered in a short time—e.g., after a few hours in hospital—but in our group the average duration of incapacity before admission to hospital was 7 months. What, then, were the factors responsible for the persistence of symptoms?

In 39 cases a main factor appeared to be fear of fresh exposure to another severe experience. Many of the cases with previous neurotic breakdown occurred in this group, but it included others—e.g., a merchant sea-captain who had behaved in an exemplary fashion under attacks until actually sunk on one occasion, after which he could not bring himself to face the sea again. As one woman, with a previously good record put it, "It is too much to bear; no one could be expected to stand it." In some of these a hysterical symptom maintained the patient's self-respect, as he believed he had been physically injured and there was no need to acknowledge fear.

Domestic and financial factors were important in 42 and the main factor in 17. Thus in many cases the loss of loved ones, home, possessions, and a lifetime's savings which might be represented by the house and its contents, proved too much against which to struggle: and understandable reactive depression carried on into a chronic depressive illness, the effort to make a fresh start proving too great. Such cases occurred especially among the more elderly patients; usually the form of illness was depression, but sometimes conversion hysteria coexisted or was the main symptom, and protected the patient from being called upon to make such an effort. Thus an elderly farmer whose wife had been killed and whose house, which he had built with his own hands, had been destroyed, developed a hysterical paralysis of the arm, which had only been bruised. The paralysis persisted until he had been brought to the point of really determining to start again.

Pensions considerations were important in only 13 cases. The usual attitude among these patients was one of resentment against the world, and they felt they were entitled to some compensation for their sufferings or to have security in the future. Although exaggeration of their experiences was especially common, only one of them could be considered a conscious out-and-out malingerer. In some instances the desire for compensation appeared to be motivated by loss of possessions or loss of self-respect, and could be met only by a pension for a hysterical illness masquerading as a physical injury.

Numerous other psychological considerations were responsible for the persistence of the illness in different cases. Thus in one case anxiety lest he be called up for the Army helped to maintain a neurotic illness after the physical injuries had healed; in another it was fear that he might have to go on with an unwanted engagement; in another it was guilt over the death of a friend whom he had not relieved at his post of duty at the proper time. Often it was a pre-existing problem that the illness helped to solve.

In 24 cases physical factors were considered to be of importance, and in 11 the final diagnosis was one of physical illness. These patients were sent into hospital for investigation, report on how far the illness had been caused or aggravated by the incident, and assessment of the permanent disability. Examples would be cases of cerebral arteriosclerosis, aggravation of Parkinsonism, or nerve injury.

Such factors as have been described were rarely single. A debilitating physical illness might coexist with domestic stress and fear of air raids in a complicated causal chain in which any such factor could be analysed into a result of some and a cause of others, but all had to be considered in treatment. A study of the factors concerned showed once again the minor importance of the actual blast in persistence of the illness. The bad cases prognostically were not those which had been the worst-bombed, but those in which some other factor such as pensions considerations or early senility played a major part.

Hospital Treatment

As has been pointed out, the diagnosis was often mixed, and cases could be considered under more than one heading. Taking the most important symptoms as criteria, they were classified as: anxiety states 37, hysteria 25, depression 22, physical 11, schizophrenia 2, left before fully investigated 3. Of these cases, one-third had left hospital by the end of a month, one-half by two months, and two-thirds by three months. The best results were obtained in those able to recover quickly enough to leave hospital in a short time. In view of the fact that these patients had been ill for an average of 7 months before admission to hospital, the period of hospital treatment required was short. When the cases were considered in two groups—one consisting of those who had been ill less than 7 months, and another of an equal number of those who had been ill more than 7 months—the results of treatment were numerically identical. This would suggest either that the illness had a natural period of recovery of some such length or that the cases had been awaiting specialized treatment such as a hospital could give them and could not recover without it. The evidence would appear to show that the latter was true in many instances, and would indicate that in the absence of other factors chronicity itself does not militate against recovery.

An attempt was made to determine how far the onset of the illness was wholly due to the precipitating incident. In 57 cases it was considered to be wholly attributable, and in a further 18 to be due to the incident but with previous predisposing personality characteristics not amounting to neurotic illness. The others were regarded as cases of neurotic relapse or aggravation of pre-existing physical illness.

The methods of treatment adopted were those ordinarily used in psychiatric practice. Persuasion, explanation, re-education, removal of symptoms by suggestion, occupational and physical therapy, were all employed in suitable cases, but the important feature in this group of patients was an assessment of the factors responsible for the persistence of the illness and the removal of these wherever practicable. Psychiatric social workers were freely employed in all their three main functions—namely, to obtain reliable information not available to the doctor, to advise and give aid in dealing with current problems, and to help patients on discharge.

The immediate results of treatment were considered in relation to symptoms (Table I) and to estimated capacity for work (Table II). Under the first heading a case was classified as recovered if symptom-free on leaving hospital, irrespective of the possible effect of future stress. Under the second heading, "same work" is defined as work of the same socio-economic level as before the illness, though not of necessity the same occupation. "Light work" refers to an occupation of less stress for the patient, though not necessarily physically lighter. Occasionally, to minimize risk of relapse, patients returned to work in a different locality, the classification then depending on the kind of work which they did. In most cases specific arrangements for return to work were made with the help of social workers and the Ministry of Labour before discharge from hospital.

Table I

	Recovered	Much Improved	Improved	No Change	Treatment Incomplete	Total
M. ..	12	19	23	13	3	70
F. ..	9	8	5	6	2	30
	21	27	28	19	5	100

Table II

	Same Work	Light Work	No Work	Unknown	Total
M. ..	32	22	13	3	70
F. ..	19	3	6	2	30
	51	25	19	5	100

Of the patients who showed no change, 2 suffered from schizophrenia and 5 from physical illness of a kind which could not be expected to improve, leaving only 12 who were not benefited by treatment.

In the case of the women the figures often refer to estimated work capacity, as many had previously been employed in domestic duties only.

Follow-up

When those with irremediable organic and mental disease (e.g., cerebral arteriosclerosis and chronic schizophrenia) were excluded the immediate results were so surprisingly good for neurotic illnesses of such duration that it was felt desirable to follow up as many as possible. Practical difficulties allowed of this being done for only 29 patients, who were interviewed by a trained psychiatric social worker, and 7 about whom information was received from other sources. The average length of time between discharge from hospital and the follow-up was over 6 months.

The follow-up enabled the condition to be compared with that at time of discharge and the actual work record to be compared with that anticipated when leaving hospital. In both these respects the condition after this interval agreed very closely with the estimated prognosis. Of the 36 cases followed up, 26 corresponded exactly, 5 did somewhat better than anticipated, and 5 not so well. They appeared to be a fair sample of the whole, and if this is so the policy of arranging for specialized in-patient treatment of neurotic casualties would appear to be well justified by the results.

Summary

Investigation was made of 100 patients referred by the Ministry of Pensions because for a prolonged period they had been receiving "war injury" allowances for neurotic illness caused by enemy action. Over and above this total very few were referred. This suggests that the number of severe neurotic casualties in the country was small.

The average age was higher than the average age of other patients attending practitioners.

Judged by ordinary standards a large proportion had good personalities prior to the incident, which in most cases was severe.

Coincident physical injury did not prevent a neurotic illness, as it often does in soldiers on active service.

Feeling a bomb was a much more severe psychological trauma than hearing one.

The factors which prolonged the neurotic illness were numerous and had to be analysed in each instance. They were often unrelated to the war.

The bad cases prognostically were not those patients who had been most bombed, but those in which some other factor played an important part.

In spite of prolonged illness and allowances these patients responded quickly and satisfactorily to hospital treatment, unlike patients with compensation neuroses in peacetime.

76% were able to return to work of some kind.

A follow-up showed that the symptomatic recovery or improvement was maintained and that they were usually able to continue at the work to which they went when discharged.

Care of the feet is an important part of the medical services of the A.T.S. Certain foot complaints, due to different shoes, unaccustomed standing, and, in some instances, to drill, occur within a few weeks of enrolment, and regular examination is necessary if the feet are to be kept in a good condition and such disorders to receive early treatment. An appeal is therefore being made for women chiropodists up to the age of 43 (50 for ex-Service women) for the A.T.S. They will be sent to a basic training centre for one month and afterwards posted, with the rank of corporal, to A.T.S. groups or training centres and will receive pay at the rate of 3s. 8d. a day. They will be supplied with a complete set of instruments and all felts, pads, and lotions required for treatments. All chiropodists work under the direction of a medical officer, and cases which do not respond adequately to treatment are referred to an orthopaedic surgeon in a hospital. It is intended to have a corporal chiropodist for every 600 auxiliaries.

THE CURE OF SCABIES, AND A NEW REMEDY

BY

G. H. PERCIVAL, M.D., Ph.D., F.R.C.P.Ed., D.P.H.

Physician to the Skin Department, Royal Infirmary, Edinburgh

The time required to destroy an acarus infestation may not be long enough to allow the structural disorganization of the epidermis caused by the parasite to have righted itself entirely by the end of the treatment period. A treated case of scabies may be free from acari—that is to say, cured of scabies—but need not present a skin entirely free from lesions. Immediately after successful treatment with any of the recognized remedies scratch marks and pin-head blood crusts, subsiding pustules, crusts, and scaly tags may still be seen on the abdomen, buttocks, thighs, and anterior axillary folds. Such residues are less pronounced after the use of ointment preparations than when the remedy has been employed in the form of a liquid to be painted on the skin. While the presence of lesions following treatment does not mean that the object has not been attained, the absence of itching may not indicate a cure, for this symptom may disappear temporarily in a case in which treatment has failed, only to return in about ten days, during which time the surviving parasites have increased sufficiently to cause symptoms. The discovery of live acari at the end of a period of treatment proves its failure at once, but failure to find the acarus immediately is no proof of cure. It can only be regarded as such if repeated examinations over a period of two weeks are negative. By this time, however, if cure is not complete, lesions and symptoms will have developed which will be visible to the naked eye and obvious to the patient, except in the very rare instances of latent scabies, if such a state exists.

Observation Period after Treatment

The majority of cases of scabies to which one or other of the known efficient remedies are adequately applied are cured, and in them no acari would be discovered. In a few uncured cases, and perhaps in a given series in all uncured cases, no acari might be found immediately after treatment, and a period of observation would be necessary to demonstrate their continued presence. Only in a very few cases can the discovery of acari immediately following treatment, and not the failure to demonstrate their presence, at once give the desired information as to the result. It follows, therefore, that only in an extremely small proportion of cases can the observation period be dispensed with if the result is to be established with certainty.

This observation period subsequent to treatment of scabies is necessary and of practical importance only when the value of a new drug is first being assessed. If it is then established that a drug in a definite concentration is capable of curing the disease when tested on a reasonable number of cases and following a definite routine, the criterion of cure, for practical purposes, when the drug is used in conditions where known new cases are numbered monthly by the thousand in a single community, is the efficiency with which the prescribed routine of application is carried out. In a large treatment centre it is not possible either to examine for acari closely enough for the examination to be of any practical value or to multiply visits by insisting on the period of observation. Apart from staff shortage, it is difficult to obtain regular attendance during the treatment period.

It cannot be asserted that the prescribed technique of treatment with any remedy is capable of success in every case, but failures following the correct application of sulphur ointment are extremely rare (Mellanby *et al.*, 1942). When the patient personally carries out the instructions the percentage of failures depends on his intelligence, home surroundings, and the care with which the instructions have been explained to him. A patient may reasonably be expected to be able to take a teaspoonful of cough mixture three times daily, and failures in the technique of this procedure must be few indeed. Similar success in the carrying out of instructions is not met with in the treatment of scabies or, for that matter, in the treatment of skin disease in general.

Choice of Remedy

The technique of the commonly used remedies is more or less similar and the choice has up to the present been governed by cost, cleanliness, time, and freedom from irritant properties. It may be, however, that the availability of the remedy will become the deciding factor.

Sulphur is the oldest remedy for scabies, and according to Hebra its indirect use dates back to the cure of Naaman's presumed attack of the disease. Its outstanding worth as an agent lethal to the mites and eggs of the acarus has been demonstrated recently by Mellanby, Johnson, and Bartley (1942). It should be noted, however, that the standard treatment for scabies is not three applications of sulphur ointment as stated by them. Authors differ slightly in the technique advised. That laid down by Walker and Percival (1939) is six applications of 5% sulphur ointment over a period of three days, preceded and followed by a bath, no bath being taken during the period of application. Sulphur is cheap and can be incorporated in a more elegant base than lard or soft paraffin if so desired, but to be efficient it must be applied in the form of an ointment to be rubbed in. This necessary use of fats and oils in conjunction with sulphur at a time when these substances are in short supply justifies the trial of possible substitutes which do not require fats and oils in their application or which need a less amount.

Tetraethylthiuram Monosulphide

Another substance has recently suggested itself as possibly being of use. There is no reason to anticipate a shortage in its supply, and this fact alone should recommend its trial on a large scale. This substance is tetraethylthiuram monosulphide, and since 1940 I have used it in the treatment of human scabies. Because of unavoidable delays it has been employed in only a small number of cases. It was found to be non-irritant to the human skin when applied in the form of the pure powder, and no case of cutaneous idiosyncrasy to it has been encountered. It has proved curative in a strength of 5% in the form of a liquid preparation in 50 consecutive cases, 21 of which were treated as in-patients in the ward of the skin department of the Edinburgh Royal Infirmary, and 29 as out-patients at scabies treatment centres. Of 25 cases treated with a 0.25% solution 4 were cured; 1 case was treated with 5% tetraethylthiuram monosulphide in a vanishing cream and was cured; 3 were treated with a prepared tetraethylthiuram monosulphide powder mixed with water to form a paste, which was then smeared on the skin, and 1 was cured. The liquid preparation used was an emulsifiable oil having the composition: tetraethylthiuram monosulphide 25%, polyglycerol ricinoleate 10%, industrial methylated spirit 65%. One part of this oil was added to four parts of water immediately before use. While the 25% concentration remained stable at room temperature it tended to crystallize out if kept at lower temperature, but gentle heating sufficed to redissolve the crystals. Unfortunately the diluted oil separated, giving a layer of pasty consistency which did not redissolve. This necessitated preparing the required 5% dilution immediately before use. The 25% solution may stain material yellow, but this discoloration washes out easily. The mixture has a slight odour, not noticeable, however, in the 5% dilution.

The liquid preparation was rubbed over the whole body, with the exception of the head, face, and neck, twice daily for three days, as in the case of sulphur ointment. The duration of treatment is an important point in the cure of scabies with any remedy, and repetition reduces the possibility of inadequate application. If staffed by a trained personnel, the scabies treatment centre can be relied on to ensure at least one adequate application even if there are difficulties in enforcing the necessary return visits (Percival, 1941).

Observations by Gordon and Seaton (1941) on the lethal properties of tetraethylthiuram monosulphide for acari in animal scabies have shown that it is more toxic for the mites and eggs and more rapid in its action than either benzyl benzoate or dimethylthianthrene (mitigal). During their experiments they were also able to prove conclusively that mites, especially larvae, can migrate from their burrows and infect surrounding clothing, which is capable of reproducing the disease if applied to another animal. These experiments on the possible transmission of animal scabies cast some doubt on the advisability of omitting to disinfest clothing in the case of human scabies, a view originally advocated by Mellanby (1941), although later modified by him.

Summary

Tetraethylthiuram monosulphide in a concentration of 5% is capable of curing human scabies. So far it has been found to be non-irritant to the human skin, and no instance of cutaneous idiosyncrasy to it has been encountered. It is cheap, clean, easily available, and economizes in fats and oils. Its trial on a more extensive scale by independent observers is suggested.

The author thanks Imperial Chemical Industries (Pharmaceuticals) Ltd., Manchester, for preparations of tetraethylthiuram monosulphide.

BENZYL BENZOATE IN TREATMENT OF SCABIES

A COMPARISON OF THE EFFECTS OF AQUEOUS AND SPIRIT EMULSIONS

BY

K. C. MALLEN, M.B.

Major, R.A.M.C.

At the request of the A.D.M.S. a series of cases of scabies was treated during a three-months period to ascertain the value of an aqueous emulsion of benzyl benzoate. During the previous 12 months many cases of scabies had been treated in this camp reception station by various methods, and it was evident that the benzyl benzoate one was the best.

The cases were not selected, every second admission being treated with the aqueous emulsion, regardless of the extent of the lesions present. The control group was treated with the spirit emulsion. The emulsions used contained equal parts of benzyl benzoate, soap, and spirit or water. The number of cases upon which these figures are based was 1,000, and the slight discrepancy in the final figure is due to the fact that benzyl benzoate was at times difficult to obtain. As a result more cases were treated with the spirit emulsion and a few with sodium thiosulphate and hydrochloric acid. The latter treatment was used to a considerable extent in the earlier part of the year, but was discontinued because of the number of cases of dermatitis that resulted.

Method

The number of beds available was 39; but at times room had to be found for more cases, and these were accommodated on stretchers. There were only two baths to be had, and these were in constant use for the bathing and scrubbing of the patients. During the three months under review the number of baths given averaged 25 per day.

On admission the patient's clothes were checked and sent to the pack store, where the articles, which included the bedding, were disinfested in a hot-air disinfestor of the Millbank type. The clothes were then stored away until the patient was ready for discharge. The patient was given a bath and scrubbed by an orderly, and was treated with either type of emulsion. He was then dressed in pyjamas and put to bed. On the following day he received the same treatment. On the third morning he was seen by the medical officer, and if there was no active lesion he was given a treatment of calamine lotion and discharged the next morning. In the cases in which there was a secondary infection, such as impetigo, he was transferred to the main block of the camp reception station for further treatment. These cases with another infection are not included in this series. Some of the cases were not completely cleared by two baths, and these had to have a third application of the treatment; a few had four applications. The numbers, however, were very small: in 28 cases three baths were required, and in 3 cases four baths.

Owing to the possibility that dermatitis, present as the result of treatment, might persist, it was necessary to adopt some kind of follow-up, and the following form was forwarded to the regimental medical officer for completion seven days after the man's return to his unit.

SUBJECT: SCABIES "FOLLOW-UP"

To: M.O. i/c ....
Reg. No......... Name................ Rank........
The a/m man was discharged from the Camp Reception Station, ..., on ...., having been treated for scabies. I should be very grateful if you would examine him on .... and return the attached proforma. It is recommended that one week's treatment of calamine lotion be given.
Lieut.-Col., R.A.M.C., O.C., Field Ambulance.

To: Camp Reception Station, ... Tel.......
....
Name................ Number........ Rank........
Condition of skin (is there any dermatitis?) ....
Is there any irritation? If so, where? ....
Do you consider there is any recurrence of scabies? ....
Date............ Signature........................

Excellent co-operation was given by the R.M.O.'s concerned, and in only a few instances was it necessary to send out reminders.

The following Table shows the numbers treated and the percentages of recurrences and incidence of dermatitis:

Treatment	No.	Cures	Recurrences	Dermatitis
Benzyl, meth.	527	519	8 (1·56%)	6 (1·2%)
Benzyl, aqueous	448	447	1 (0·24%)	14*(3·1%)
Thiosulph.+HCl	24	24	1 (4·0%)	1 (4·0%)

* 11 of these occurred at a time when it was impossible to obtain sapo moll. *B.P.*, so a brown soft soap issued by the O. i/c Barracks was used instead. This I think definitely contributed to the incidence of dermatitis. This soap was not used in the preparation of the spirit emulsion.

Conclusions and Summary

One thousand cases of scabies were treated, half with an aqueous and half with a spirit emulsion of benzyl benzoate. It would appear from the results that the aqueous is as efficient as the spirit emulsion. The advantages as regard cost are obvious.

The amount of dermatitis is slightly higher and the incidence of recurrence very much lower. There are a few general points worth noting about the cases sent in for treatment. The incidence of penile, abdominal, and thigh lesions is amazingly high—79%—and the fact that only one case had the lesion confined to the interdigital spaces bears out the theory that most people consider that the disease is due to close body contact. This is also borne out by the fact that the majority of these men gave a history of having returned from leave during the previous 7 or 8 days or admitted recent venereal contact.

K. Mellanby (*British Medical Journal*, 1941, **2**, 405) states that the possibility of the spread of scabies by means of blankets was very remote and that the spread by underclothes was possible under conditions which appear to offer the maximum chance of infection. It is hoped that these conclusions will be further tested, so that this point can be cleared up. If what he states is true then surely the amount of time, labour, and money spent on the disinfestation of clothes is useless.

I should like to thank all the medical officers who have helped in this investigation for their assistance, and also to pay tribute to the nursing orderlies whose work made the above results possible.

W. N. Warvi and R. W. Rawson (*Arch. int. Med.*, 1942, **69**, 90) record a case of torula meningitis in a man aged 39 in whom the characteristic symptoms were the insidious onset and the intermittent but progressive course, going on to a fatal termination. The increasing intracranial involvement caused the following symptoms: severe headache, visual, sensory, and motor disturbances; weakness; projectile vomiting; disorientation; coma; and respiratory failure. The case is the eighth reported example of the association of Hodgkin's disease with torula meningitis.

TREATMENT OF VARICOSE VEINS IN SOLDIERS

BY

ERIC L. FARQUHARSON, M.D., F.R.C.S.Ed.
Major, R.A.M.C.

The treatment of varicose veins by injections alone presents many difficulties when it is applied to military patients. In the first place, it is common for the affected veins to show the condition of *ectasia* rather than true varicosity, and veins of this type do not respond at all well to injection methods. Secondly, regular or systematic treatment is often quite impossible, owing to the continual movement of troops, re-postings, etc. A large proportion of soldiers reporting sick with varicose veins have had a few haphazard injections at irregular intervals; these may have had no effect whatsoever, or the benefit conferred was only temporary—a fact that has not escaped the soldier's notice and encourages him to distrust or to refuse further injection treatment.

Any form of operative treatment recommended must be considered in the light of its effect on the man's efficiency as a soldier, and precedence must be given to the method which is most likely to make him fit for full duty within the shortest possible time. Extensive radical excisions (Payne, 1941) have no place in the treatment of military patients. Apart from the long period of convalescence required, the scars which remain often form a basis for continued complaints.

The Trendelenburg operation, when it is not combined with injection, is frequently most disappointing. There may be little or no diminution in the size of the varices, or, alternatively, any improvement noted may be only temporary, as the affected veins dilate again, owing to the opening up of collateral anastomoses with the deeper channels. When combined with injection, the Trendelenburg operation has many advocates, and a 90% cure has been claimed (Oldham, 1941) for this method of treatment. Many workers, however, including the writer, have not been so successful in the results obtained, in that the thrombosis is apt to be incomplete and patchy in distribution. Furthermore, a formal Trendelenburg operation is not to be undertaken lightly, and there is no question that military patients must be admitted to hospital.

Subcutaneous Ligature combined with Injection

The accompanying photographs illustrate this method. In the case treated the varicosity involved the whole of the great saphenous system and had been present for 12 years. Complete thrombosis of all the dilated veins was obtained from one treatment.

In the method of subcutaneous ligature, a stitch is passed round the vein, and is tied over a swab placed on the skin surface. Except in cases where the varicosity extends right up to the saphenous opening (see below), the vein is ligatured *at its highest visible or palpable point.* This may be situated in the thigh (often at the junction of the upper and middle thirds) or at the medial side of the knee. In the former case a second ligature is applied at knee level. Very occasionally a third ligature is required.

An injection of sclerosing solution is made into the vein immediately below each ligature. The injected fluid takes effect in a "closed" and relatively small segment of vein, where the blood is almost completely stagnant and there is no dilution from backflow. As the result an effective thrombosis is invariably obtained.

Technique of Ligature.—The ligatures are most easily applied with the patient standing up. Silkworm-gut, threaded on a fairly fine curved skin needle, is employed. The needle is passed round the vein, transfixing the skin about 1/4 in. on each side of it, and the gut is tied over a small roll of gauze the thickness of a finger. A local anaesthetic is quite unnecessary.

Injection.—On the suggestion of Lieut.-Col. S. Sokolowski of the Polish Army Medical Corps, 20% saline solution has been used. This has the great advantage of being readily obtainable, and it has been most effective. Up to 50 c.cm. can safely be injected at one treatment, so that a widespread thrombosis can usually be obtained. Ten to 20 c.cm. i injected below each ligature, the amount depending upon th extent and varicosity of the veins under treatment. Crampin pain is felt in the limb about 15 seconds after injection ; i may be fairly severe for 30 seconds, but usually passes of completely within 2 minutes.

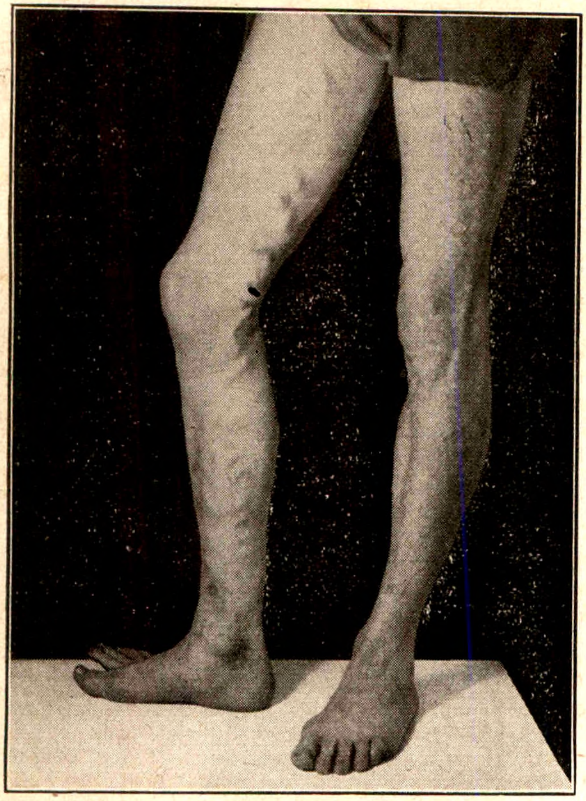

FIG. 1.—Showing the extent of the varicosity.

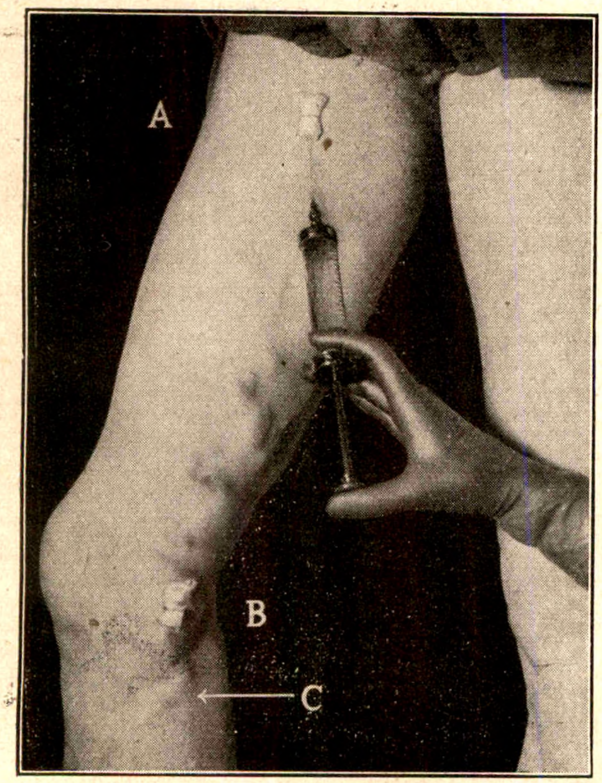

FIG. 2.—Subcutaneous ligatures at A and B. The first injection was given as shown, and the second at the point marked C. 20 c.cm. of 20% saline was injected in each situation.

If the dilatation extends right up to the saphenous opening subcutaneous ligature is impracticable ; an open ligature i therefore carried out, but no widespread dissection is attempted The vein is exposed by a 1/2-in. incision at its highest point, anc is divided. Ten to 20 c.cm. of saline solution is injected intc the cut lower end before this is ligatured.

After-treatment.—The presence of the ligatures *in situ* causes comparatively little discomfort, and, considering the extent o the thrombosis produced, the reaction is not severe. It is customary, therefore, to return the patient to his unit, with a recommendation that he be excused all duties for 48 hours and that he be kept on light duty until he reports back for removal of the ligatures in 7 days' time. Patients whose veins are very dilated are detained in hospital for one or two nights. During this time the limbs are firmly bandaged to compress the veins and to reduce the size of the ultimate thrombosis. Open ligature of the vein at the saphenous opening does not necessitate hospitalization provided that, in contrast to a formal Trendelenburg operation, it is done through a small incision and no extensive dissection is attempted. After removal of the ligatures a further period of light duty may be required, depending upon the reaction present, but most patients can return to full duty within two weeks of the original treatment.

Results of Treatment.—The immediate results are excellent. Of 150 soldiers treated by this method the great majority required only one treatment for each affected limb. About half the patients had two ligatures applied—one in the thigh and one at knee level. The rest, in whom the varicosity or ectasia did not extend above the knee, were treated by a single ligature at this level. As already stated, most of the patients returned to full duty within 2 weeks of the original treatment. The late results cannot at present be assessed, owing to the difficulties of follow-up in Service patients. It has not been possible to re-examine more than 30 patients, and these at intervals of from only 2 to 9 months after treatment. In these, however, the affected veins had all contracted down to hard slender cords, in which any possibility of re-canalization seemed to be quite out of the question.

Discussion

It is maintained that the method of subcutaneous ligature combined with injection is particularly suitable to the treatment of military patients, in whom injections alone are unsatisfactory and all forms of radical operation are contraindicated.

The method is not, of course, a new one (Russell, 1941 ; McCurrich, 1941), and I am aware that it has been extensively criticized (Eckhoff, 1941 ; McAusland, 1941 ; Schick, 1941 ; Oldham, 1941), mainly on the grounds that the saphenous vein cannot be ligatured at its highest point. Treatment by ligation at any lower level is stated (Schick, 1941) to be followed eventually by as high a percentage of recurrences as after simple injections alone, and it has suffered the sweeping condemnation (Oldham, 1941) that it is as futile as would be the removal of the distal half of a hernial sac. The first assertion is at least open to question ; the second can be categorically denied. Complete thrombosis of *all* dilated veins in the great saphenous system can usually be obtained *at one treatment* by two well-placed ligatures with an injection below each. Most patients return to full duty within two weeks of treatment, and hospitalization is rarely necessary. No claims are made regarding the late results. Fresh varices may undoubtedly develop in the years to come, as they may with any form of treatment. It is suggested that this, like other post-war problems, does not require serious consideration at the present time.

Medical Memoranda

Primary Cerebral Sinus Thrombosis

In view of the interest recently shown in this subject, especially in this *Journal* (see bibliography), the following non-puerperal case of "primary" cerebral sinus thrombosis seems to merit publication.

Case Report

The patient, a single woman aged 30, of asthenic build, was admitted to hospital suffering from restlessness and mental confusion. She had been in bed for 2 to 3 weeks at home with "bronchitis." Whilst in bed she developed left and, subsequently, right femoral thrombophlebitis. Mental symptoms were present during the last few days. There had been no vomiting and no previous illness. She had recently changed her occupation, and was depressed and "run down" owing to unhappiness at work.

On examination her condition was as follows: conscious but confused; headache severe; temperature 101°, pulse 106, respirations 28; slight residual swelling of ankles; no acute phlebitis; both knee-jerks slightly exaggerated; blood pressure 115/70; ears and fundi normal. Nothing else abnormal was observed in any system. Investigations on June 11, 1942, showed:—Lumbar puncture: pressure increased, Queckenstedt's test normal, C.S.F. examination normal in every respect. Nothing abnormal in urine. Non-protein nitrogen 26 mg. per 100 c.cm. Blood Wassermann reaction negative. Blood culture, coliform bacilli. All agglutination reactions negative. By June 15 she had developed a positive Kernig's sign, slight neck rigidity, and left extensor plantar response. Limb movements were apparently completely normal. Radiographs revealed skull and chest to be normal. A differential white count disclosed marked lymphocytosis. Pyrexia continued despite sulphonamide therapy. On June 17 lumbar puncture showed: pressure increased; C.S.F. contained numerous red cells, but otherwise was completely normal. Blood film, normal. Faeces, nothing abnormal.

The persistent normality of the majority of the investigations was puzzling, especially in view of the complete absence of any sign of paralysis or convulsions, but the possibility of thrombosis of the superior longitudinal sinus was entertained. The patient, however, became very considerably weaker and more drowsy, and she died on June 24.

Post-mortem Examination.—C.S.F. yellowish, not turbid; no evidence of meningitis; massive thrombosis of superior longitudinal and both lateral sinuses (apparently an aseptic thrombosis); bilateral thrombosis of superficial cerebral veins; no changes elsewhere in the brain; no necrosis, no hydrocephalus. The thromboses gave a definite impression of having originated in the superior longitudinal sinus, and of having spread thence to the lateral sinuses and to the superficial cerebral veins. Ears, nose, and throat, normal. Chest: purulent bronchitis, lungs normal. Abdomen: bilateral thromboses of common and external iliac veins, continuous with clot in both femoral veins; kidneys somewhat fibrosed; spleen normal; liver contained focal necroses. Bone marrow somewhat hypoplastic. Other organs normal.

Discussion

This case seems to bear out the interesting suggestion of Martin (1941), arising out of the work of Batson (1940): the possibility of "metastatic" thrombosis of the cerebral sinuses, via the vertebral veins, arising from the pelvic veins. Batson specifically mentions that this would be apt to occur during coughing—it is noteworthy that the initial complaint in this case was "bronchitis." The absence both of convulsions and of paralysis is distinctly unusual; this may perhaps conform to the impression gained at necropsy that the venous thrombosis developed subsequently to the superior longitudinal sinus thrombosis, possibly only immediately before death.

I should like to express my thanks to Dr. H. C. Haslam-Fox, medical superintendent, for permission to publish this case, and to Dr. R. Y. Dawbarn, who performed the necropsy, for the pathological reports.

R. H. M. Stewart, M.B., Ch.B.,
Resident Medical Officer, Ormskirk County Emergency Hospital.

Reviews

WAR INJURIES OF THE *CHEST*

War Injuries of the Chest. Edited by H. Morriston Davies, M.Ch., F.R.C.S., and Robert Coope, M.D., F.R.C.P. (Pp. 131. 6s. plus 6d. postage.) Edinburgh: E. and S. Livingstone. 1942.

In the literature on war wounds in general there has been a gap covering the treatment of chest injuries which could only be filled, and that incompletely, by reference to scattered articles and papers. The editors of this book have attempted to remedy the situation and to produce a concise account of the treatment of chest injuries for the use of officers in the field and at casualty hospitals. In this they have partially succeeded.

The book is well arranged and begins with a useful account of the special anatomy, physiology, and pathology of chest injuries, but this is somewhat marred by inaccurate diagrams of the bronchial tree and the broncho-pulmonary segments. Later chapters are concerned with the treatment of special injuries and contain much that will be disputed by those who have had practical experience of chest casualties. For instance, the statement that "so long as a patient is in need of resuscitation he is not fit to be *x*-rayed" is not confirmed by experience, for an essential *x*-ray examination causes little disturbance if a portable machine is used. Again, the authors are unduly afraid of operating on a shocked patient and, in consequence, their indications for primary operation are too few; but experience has shown that with skilled anaesthesia and continuous resuscitation the patient's condition improves steadily during any operation which relieves his circulatory and respiratory embarrassment. The chapters on haemothorax leave much to be desired: few would agree that a sterile haemothorax should be washed out with saline, that a general anaesthetic is necessary for the first aspiration, or even that the aspiration of a haemothorax is "comparatively simple." No clear directions are given for the treatment of an infected haemothorax; instead a series of possibilities are presented which may confuse the inexperienced. The authors state that a blocked intercostal tube should be cleared by the injection of saline, without mentioning the danger of air embolism if the pleural space is at all rigid. They also advocate the use of atropine in the treatment of crush injuries and in pulmonary oedema, but in the former case it is dangerous owing to the production of sticky sputum while in the latter it is surely unphysiological. Finally there is a chapter on anaesthesia, which condemns nitrous oxide, although this gas is extensively used in chest surgery, and misrepresents the properties of trichlorethylene.

The great disadvantage of this book is that it fails to give dogmatic instructions. The medical officer dealing with chest casualties needs to be told as simply as possible what to do, and it is useless to present him with a number of alternatives unless the indications for each are given clearly and concisely. If these defects could be remedied in future editions this little book, which contains much useful information and which is a handy size for the pocket, would be a helpful companion to the casualty officer.

SCIENCE AND HUMANITY

The Values of Science to Humanity. By A. G. Tansley, F.R.S. The Herbert Spencer Lecture, Oxford University, June, 1942. (Pp. 31. 1s. 6d.) London: George Allen and Unwin. 1942.

Prof. A. G. Tansley's Herbert Spencer Lecture delivered on June 2 would have been approved by the sturdy individualist in whose honour the lecture was founded and, in these times, when the maxim *fas est ab hoste doceri* is reiterated with angry vehemence, brings to the discussion of a controversial topic a welcome urbanity. The concluding sentence of the lecture is the lecturer's inference from the evidence he has presented: "If we desire to keep alive and vigorous the ultimate springs of our material welfare, and—not less important—to maintain and extend the place of science in our culture, we must jealously guard its freedom and its independence."

Those who have emphasized the importance of scientific planning and organized research have, of course, many excuses for anger. It is only too obvious that few, if any, Ministers of State in this country know anything of science, pure or applied. Recently a Minister answered the rhetorical question whether it would not be better to teach boys the principle of an internal combustion engine rather than the elements of Latin grammar, with the bland remark that it might be hoped that a boy who had studied Latin would be able to take knowledge of the internal combustion engine in his stride. Also the historical fact that down to the end of the 18th century most fundamental scientific discoveries were made by gifted amateurs is subject to Macaulay's reply to the complaint that 19th century women knew less Latin and Greek than Lady Jane Grey. If Lady Jane Grey had not read the classics what was there for her to read? In the 18th century scientific research could be the pursuit only of wealthy amateurs or of men with courage to endure privations.

But it remains true that it is no more possible to plan or organize the work of a Newton, a de Moivre, or a Helmholtz than that of a Wordsworth or a Beethoven; that when we recognize or even suspect the existence of original power in scientific research, nothing should be done to divert the inquirer from the train of thought or work to which his curiosity attracts him. A great palaeobotanist or pure mathematician contributes more to the stock of humanity than a second-rate engineer.

The medical profession recognized this more than a generation ago. Men still living remember the time when the teaching of what are now called the fundamental sciences was mainly technological. Now the laboratories of medical schools contribute as actively to the output of "pure" research as those in which no medical students at all are taught. No great change is a wholly unmixed benefit; some may hold that the movement has gone too far; but all would agree that the good has predominated over the evil.

Prof. Tansley remarks that the statement "curiosity is a sublimation of the desire for power" is "just psychological nonsense." Curiosity is a primary instinct and tends in common speech to be depreciated because of the secondary meaning—"inquisitiveness in reference to trifles or matters which do not concern one." There lies the danger. It is so very easy for the eminent A to believe that *his* curiosity is of service to humanity while B's curiosity is mere inquisitiveness, and so we reach within the circle of science that childish arrogance which inspired the Minister's remark concerning Latin mentioned above. Our profession will be alive to the danger.

ELECTROCARDIOGRAPHY

Essentials of Electrocardiography. For the Student and Practitioner of Medicine By Richard Ashman, Ph D, and Edgar Hull, M.D. Second edition (Pp. 373. 21s.) New York and London: The Macmillan Company.

The second edition of *Essentials of Electrocardiography*, by Drs. R. Ashman and E. Hull, makes its appearance four years after the first publication. Most of the chapters have been rewritten and the volume is considerably enlarged. These changes and additions have resulted in the presentation of an up-to-date review of this branch of cardiology. For a volume which is not an exhaustive treatise there is perhaps undue emphasis on the physiological basis of the electrocardiogram; much of the third and fourth chapters will be outside the range of beginners in the subject and, indeed, of most general clinicians, and yet this book is specifically addressed to students and practitioners of medicine. The arrangement of the later sections of the book might be modified: discussions on the electrocardiogram in many and various non-cardiac maladies have been grouped together in three chapters on the electrocardiogram in diseases of the heart. More space might have been allocated to these aspects of the subject, since they represent an important part of the "growing edge" of electrocardiography. The bibliography must receive criticism: it is too sectional and not representative of the shares which have been contributed by many important sources to the sum of electrocardiographic knowledge. Much of the pioneer work has been done on the Continent, particularly on the metabolic background of cardiographic abnormalities; scarcely any references are made to these sources, while an unduly high proportion of the bibliography relates to American publications. Reproductions of 122 electrocardiograms show uniform excellence and they illustrate well the principles expounded in the text.

Notes on Books

There is much to be said for making the industrial worker aware of the general health problems in industry and for instructing him in elementary rules of hygiene, so that he may keep himself fit in both his own interests and those of the country. The same, of course, applies to other sections of the community, among whom on the whole there is a gross ignorance of rules of hygiene and no very great enthusiasm to apply what lessons have already been learnt. Nevertheless those who believe in health education must "plug" their story for all they are worth, hoping that in time a real health-consciousness in the public will be aroused. *Health of the War Worker*—a handbook prepared in co-operation with the Socialist Medical Association by the Labour Research Department (6, High Holborn, London, W.C.1; 6d.)—has one advantage in that the medical advice tendered is obviously that of someone who knows industry from the inside. The booklet acquaints the worker with those parts of the Factory Act relating to health, both personal and institutional. Nevertheless it is marred in places by an unpleasant nagging tone. The workers, for example, are frequently adjured not to be "put off by glib assurances," and there is one slightly comic distortion of fact when the writer says, in the section under heating, "fans are very plentifully distributed in West End clubs, but are much too rare in factories . . ." It is difficult to see how the puzzled worker will profit from a disquisition on the factory medical service, in which, he is told, "since doctors are liable to be called up for the armed services but not for industry, it is often the left-overs who find their way into factory jobs." And, again, to remark that the appointment of a doctor by the management "often leads to a feeling among the workers that the doctor is the management's 'yes-man,'" and to leave the worker without any assurance that this is in fact not the case, is hardly likely to help forward that co-operation between worker and doctor which the writer of this pamphlet considers to be desirable. In fact, if he had given a little more information about health and first-aid and a little less space to airing his views the value of the pamphlet would have been much enhanced.

Der Eisenstoffwechsel und Seine Klinische Bedeutung, by A. Vannotti and A. Delachaux, is published at 12.50 Swiss francs by Benno Schwabe of Basle. This monograph on the metabolism of iron and its clinical significance is an account of the researches of the Lausanne School and a review of the literature. It has been carried out with the support of the J. Macy Jr. Foundation of New York and will be of special value to biochemists and haematologists who are engaged in the study of this difficult problem. The authors have used a more comprehensive technique than other workers, estimating the iron in the serum in four different fractions. They stress the high iron content of the nuclear chromatin, and relate this to the manufacture of haemoglobin in the erythroblasts, of myoglobin in the muscles, and of cytochrome, oxidase, and catalase in the parenchymatous cells. We are now well informed about anaemia of the blood due to deficiency of haemoglobin, but anaemia of the tissues and deficiency of cytochrome and myoglobin due to lack of iron constitute a further possibility. In this way some of the epithelial and neurological symptoms of anaemia may be better explained and correlated with the similar effects of avitaminosis.

Lewis's Medical and Scientific Lending Library has issued a new Supplement to its main Catalogue, covering the period 1938-41. It may be obtained from 136, Gower Street, W.C.1. The price is 4s. (to subscribers 2s.).

Preparations and Appliances

PREPARATIONS OF VITAMIN B_1

Vitamin B_1-Boots conforms to the specification for aneurine hydrochloride described in the *Third Addendum* to the *British Pharmacopoeia* and is identical with, and has the same biological activities as, the natural vitamin. Vitamin B_1 is specific in the treatment of beriberi and has been recommended for a wide variety of conditions, including alcoholic neuritis and nutritional neuritis. Partial deficiency is likely to occur in patients on special diets—e.g., a diet for gastric and duodenal ulcers, high carbohydrate diets employed in nephritis, and restricted diets for obesity. Conditions of increased metabolism such as pregnancy and lactation increase the requirement for this vitamin. Vitamin B_1-Boots is supplied in tablets of 1 or 3 mg. for administration by mouth, and as a sterile solution in ampoules containing 5 or 25 mg. for intramuscular injection in cases of achlorhydria associated with vitamin B_1 deficiency.

PHYSIOLOGY OF THE VOCAL CORDS

The study of the manner in which the vocal cords act and move to produce the voice was first made possible by the introduction of the laryngeal mirror by Garcia in 1854. Dr. Thomas French of Brooklyn made a notable contribution to this study by photographing the vocal cords in action, and published his results in 1886 in a paper entitled "The Laryngeal Image Photographed during the Production of Tones in the Singing Voice." French noted that different individuals often employ different mechanisms in the production of the voice and that the appearances of the larynx in similar circumstances are often very different. Therefore no single description of the position of the vocal cords for the production of any given tone can apply to every larynx or even to the same larynx in varying circumstances. There is, however, a general scheme, in the study of which Dr. I. I. Pressman[1] has made further great advances by the application of ultra-slow-motion photography, the pictures being taken during phonation at the rate of 4,000 frames a second, which represents a slowing to 1 : 250 in the normal rate of vibration.

It is pointed out that two persons with exactly the same range and with voices strikingly similar are not likely to produce the same tone in exactly the same way. If one uses less expiratory force than the other in producing an exactly equivalent tone the diminished air pressure must be compensated by a closer approximation or increased tension of the vocal cords. It may be necessary to bring the posterior ends of the cords into contact for damping, which was not necessary for the person using a greater force of expired air. Equivalent tones are thus accompanied by a different laryngeal appearance in one as compared with another, and a particular laryngeal picture cannot be ascribed to the production of *any* given tone. Nevertheless certain changes take place as an ascent is made to its highest possible tone from the lowest which a particular larynx can produce. The cords are adducted by the crico-arytenoideus lateralis on either side, the antagonistic posticus muscles relaxing reciprocally. The closure is partial, leaving a broad longitudinal opening; the tension of the cords is not increased. Further closure is caused by contraction of the interarytenoid muscles, which slide the arytenoid cartilages together and close the posterior commissure. The vocal processes of the arytenoid cartilages, however, remain still splayed out and need further rotation for complete closure. This is performed by the thyro-arytenoideus muscles, which rotate the muscular processes inwards so that the vocal processes approximate, this movement completing the closure of the vocal cords with the exception of a chink remaining anteriorly. At the same time the tension of the cords is increased. Complete closure is produced by the action of the cricothyroid muscles, which, tilting the cricoid and thyroid cartilages in opposite directions, further increases the tension, closes the anterior chink, and elongates the cords. The moving-picture photographs of the larynx taken at the Bell Telephone Company Laboratories show this elongation quite clearly. To produce these effects both the arytenoid and cricoid cartilages must be fixed. The arytenoids are fixed against the cricoid by the crico-arytenoideus posticus muscles, so that the cords can become tense and elongated. The cricoid itself is fixed against the spinal column by the inferior constrictor of the pharynx. The anterior fixation of the thyroid cartilage to maintain the tension is accomplished by the cricothyroid muscles. The moving pictures show that, contrary to the older teaching, a preliminary complete adduction occurs before the vibratory movements in the cords are initiated. In this position of adduction fine intrinsic movements of the cords occur independently of any arytenoid movements. These are movements of segments of the cords as contrasted with movements of the whole cord and are produced by selected fibres of the thyro-arytenoideus muscles, which pull apart equal lengths of each cord against tension to establish a final glottic pattern in which the vibrations will take place.

Thus the final position assumed by the vocal cords in producing a tone, in preparation for vibration, is the product of two muscular forces, one of which causes adduction and tension, and the other counters this over a varying length of cord, exerting a damping effect. The lowest tone, not ordinarily in use, is produced by a general relaxation of the cords, which are foreshortened, leaving a relatively wide gap, which is not so wide or definitely triangular as in inspiration. This gap extends from the anterior commissure but is much wider behind. In the ascent of the scale there is a gradual transition in which the cords become straighter and more tense. As the cords elongate the tension increases and the edges of the cords lie almost parallel, and finally exactly parallel. When the cords have become as taut and elongated as possible, a break occurs and the damping process comes into action to yield still higher tones. A varying length of the posterior part of each cord is damped and prevented from vibrating by being brought into apposition with the corresponding part of its fellow. The anterior segment is then foreshortened functionally and a higher tone is produced, for only these portions anterior to the damped segments can vibrate. Finally, the cords approximate for so much of their length that the glottic chink is only a tiny orifice anteriorly.

On mirror examination the vocal cords seem to move from the lateral to the median adducted position as rigid bands, but the moving pictures show that this is not the case. The movement is undulating, beginning anteriorly and passing as a wave to the posterior segments; the anterior segments approximate first, followed by the middle and then the posterior segments. The air escaping under pressure between the cords everts the free margins of the cords, which spring back by their own elasticity, thus producing vibrations apart from any gross movements of adduction and abduction. The ultra-slow-motion pictures show that at a low pitch the vibrations of the cords are very complex, becoming less so as the pitch is raised. The cords become firmer and longer during the ascent of the scale. They open from below, the opening continuing upwards and outwards. Closure likewise begins from below, and as the cords open and close a ripple passes laterally over the upper surface. At extremely high pitches only the edges close to the glottis are seen to vibrate, and as the pitch rises the vibrations are confined more and more to a diminishing anterior segment, while the posterior segments remain firmly in contact. In whispering the sliding movement of the arytenoid cartilage on the cricoid towards the median line does not take place, because the interarytenoid muscles do not contract. A wide triangular gap is therefore left in the posterior part of the glottis, and a pronounced leak of air results. The anterior segments of the vocal cords act as in ordinary speech. If the pitch of the whisper is raised the anterior oral hiatus becomes narrower and the cords touch at about the middle third, but the triangular chink posteriorly persists. This has a practical application, because it is apparent that whispering can be as harmful as shouting, for the vocal cords can meet and injure each other during whispering as well as during ordinary speech. Yet often whispering is allowed when ordinary speech is forbidden.

PASTEURIZATION OF MILK

Pasteurization began to be used on a commercial scale in the large towns of this country about the beginning of the present century. Its object was to improve the keeping quality of milk, not to prevent milk-borne disease. It consisted usually of heating milk quickly to about 170° F. and immediate cooling—the "flash" process—and its product had the characteristic flavour of heated milk and a diminished cream-line. From the aesthetic point of view, therefore, it was unattractive, and rapid souring was not uncommon as the result of defects in many commercial plants. It soon became evident, however, that milk submitted to even this imperfect process was more seldom associated with the occurrence of epidemics than raw milk. The processes were under no Government control, and the first moves made by the Ministry of Food in 1918 toward the encouragement of high-quality milk—apart from the rather ineffective measures exercised by local authorities under the Diseases of Animals Acts, Milk and Dairies Regulations, the Public Health Acts, the Infectious Disease (Prevention) Act, and various local powers—aimed at the sale of clean and tubercle-free raw milk under special licence. The farming interests, backed by such disinterested enthusiasts as the late Dr. Stenhouse Williams of the National Institute for Research in Dairying, Reading, were strongly opposed to any statutory recognition of pasteurized milk. Nevertheless, when the movement passed to the Ministry of Health, pasteurized milk was included as one of the special designations in the Milk and Dairies (Amendment) Act of 1922. By this time the more fool-proof methods of "retarding" and "holding" had come into vogue, and pasteurized milk not only was a more elegant product but also gave reasonable assurance of freedom from pathogenic micro-organisms. Still the bitter opposition of dairy farmers and their supporters continued, so that when the British Medical Association began an expensive advertising campaign a few years before the present war, advocating safe milk in the public interest, it had the greatest difficulty in overcoming the reluctance of the daily press to accept the advertisements. During the present war the operations of the Ministry of Food, the Ministry of Agriculture, and the Milk Marketing Board have removed the economic motive behind the opposition of farmers, and, for the present, pasteurization is being rapidly extended without controversy. Perhaps these or similar purchasing arrangements will survive the war, but if they do not it is possible that the resistance will be resumed.

This prolonged controversy has presented an outstanding example of the disingenuous manipulation of scientific discovery to support a losing cause, and it has not been easy for medical practitioners and others who believe in pasteurization to put their finger on the flaws in the pseudo-scientific arguments used against it, with which the farmers and legislators have been well primed. This difficulty no longer exists. A most complete compilation and analysis of our knowledge of milk, its composition, and the effects of heat on it has been made by Prof. G. S. Wilson.[1] The contentions that pasteurization reduces the nutritive value of milk, that it reduces resistance to disease, that it predisposes to dental caries, that it removes an immunizing influence by destroying bovine tubercle bacilli, that pasteurized milk is unpalatable, that pasteurization fails to destroy pathogenic micro-organisms, that it removes the incentive to produce clean milk or eradicate disease in herds, that milk may become infected after pasteurization, and that pasteurizing processes are uncontrolled, are fully dealt with. The examination of all reliable, and some unreliable, scientific work on the various aspects of the subject is exhaustive. The number of articles referred to in the text runs to 333, and many of the facts they record are very fully discussed and criticized. Among the diseases which may be conveyed by milk Wilson makes no mention of poliomyelitis. Epidemics caused by milk have been recorded by American workers, and recent bacteriological and epidemiological investigations as to the general mode of infection in this disease add to the probability that these records are authentic. Apart from this there is practically nothing left that could be said on the subject, and what is said is most admirably expressed.

BLOOD TRANSFUSION IN THE U.S.S.R.

In watching, through the medium of communiqués and radio, the gigantic struggle between our Russian ally and the common enemy of mankind, medical men in Great Britain have a double concern. First, they share with the ordinary citizen a boundless admiration for the heroism of the ordinary Russian soldier and those who lead him. Secondly, medical men have a special concern in the suffering of Russian men and women and in the ways and means Russian medicine adopts to meet its Herculean task of caring for the sick and the wounded under conditions almost unparalleled in the history of civilization. We hope to be able, from time to time, to make British readers more fully acquainted with the aims and achievements of Russian medicine and Russian doctors, because we believe that one of the surest foundations of trust and friendship between our two great countries will be a close understanding between like professional groups. Understanding does not necessarily imply agreement. In this country doctors on the whole share the view of the brilliant group of men who met in London in 1645 to form the "Invisible College" that later became the Royal Society. At the height of our revolution in the seventeenth century they decided to bar "all Discourses of Divinity and State Affairs" and to confine themselves to "Physick, Anatomy . . . and Natural Experiments." The modern Russian doctor would probably not agree with this view of the men who contributed so much to knowledge under the guiding influence of John Wilkins, the Warden of Wadham College, Oxford. But we may be sure that there is much for us to learn from Russian organization of medical services, and that we in our turn also have much knowledge and experience to give that are of value. The one firm common ground we both share is the fundamentals of the science of medicine—"Physick, Anatomy, Natural Experiments," and on these can we enlarge the community of interest.

On another page in this week's *Journal* we are privileged to print an article on blood transfusion in the U.S.S.R. by Prof. A. Bagdasarov, Director of the Central Blood Transfusion Institute in Moscow. This Institute was founded in 1926, and from that date organization and research have proceeded hand in hand. In 1935, for example, the officially registered cases of blood transfusion numbered 22,000, and by 1940 this figure had risen to 200,000, exclusive of transfusions given on the Finnish front. In 1932 there were only 80 regional institutes, but by 1941 these had increased in number to 1,500. In a country that covers about a sixth of the land area of the world problems of collection, preservation, and transport of blood are indissolubly linked, and to find an answer to these was an urgent matter for scientists in the U.S.S.R. "Nowadays," Prof. Bagdasarov writes, "we consider it an ordinary matter to ship conserved blood by aeroplane over distances of hundreds and even thousands of miles into the most distant corners of the tundra and taiga, and into the steppes and deserts of the south-east regions of the Soviet Union." These, too, are matters of urgency for the British Empire, with its armed Forces spread over the surface of the globe, and a corresponding complexity of medical organization. For us the sea is what land is to the U.S.S.R., and for us the problem of sea transport is added to that of transport by aeroplane.

[1] *The Pasteurization of Milk*, by G. S. Wilson, M.D., F.R.C.P., D.P.H. With a foreword by Sir Wilson Jameson, M.D., F.R.C.P., D.P.H. Edward Arnold and Co. (18s.)

Prof. Bagdasarov brings forward a number of interesting technical points. He finds that blood conserved in a glucose-citrate solution is suitable for transfusion up to 25 days, or 20 days when transported. There appear to have been no complications in the transfusion of large quantities of group O blood. "During the twelve months of war," he writes, "literally hundreds of tons of blood have been thus applied to wounded men in all stages of evacuation, and with truly tremendous success." Prof. Bagdasarov speaks enthusiastically of plasma as a transfusion agent, stating that it is used in the front line especially in cases of shock and in the treatment of burn cases. The red corpuscles left after the separation of the plasma are, so to say, refloated in a physiological fluid, and in this "modified I.P.K. 'fluid'" erythrocytes stored at 4° to 6° C. show no marked change up to 12 days. Such conserved red cells are transfused to cases of anaemia. Prof. Bagdasarov concludes with some interesting observations on plasma substitutes, and a note on the great army of donors who "have streamed into the numerous blood transfusion institutes and stations." His article will, we are confident, be widely read and with high appreciation of the great service rendered by the organization he directs.

EPIDEMIOLOGY OF THE COUNTRYSIDE

The Milroy Lectures of 1942 add another chapter to those annals of the countryside which Dr. W. N. Pickles is writing for our instruction and enjoyment. Dr. Pickles has much of the literary charm of Austin Dobson, and uses his skill with equal felicity in making a vignette of happy country folk travelling in a motor omnibus to the market town or a graphic story of an epidemiological event.

> "I do not think the country doctor, possibly in his ignorance, has any doubt about a true influenza epidemic. Our last visitation was in 1937. Its ferocity lasted but three weeks and the busy life we all expect in a scattered country practice was transformed into a nightmare. There has been no similar epidemic since, but the first three months of most years produce a number of cases of feverish colds. The spread of the epidemic in 1937 suggested a much more infectious disorder. Ten per cent. of the population were sufferers, and all in the short space of three weeks. Two per cent. only were sufferers in 1940 and these were spread over three months. In the epidemic of 1937 the onset of the illness was abrupt. Some will remember the influenza of the early 'nineties when people collapsed in the streets and had to be carried home, and I, myself, saw collapses of this sort at 'divisions' in a ship of the Royal Navy in 1918. Without these dramatic incidents the patients in 1937 did become ill and unfit for work with very little warning. In the illness of 1940 and similar years, the patients tell us that they have been battling for several days but have had to give up at last. As I have seen it, in true influenza there is great uniformity in the symptoms, the patient is prostrate, there is a short unproductive cough, the tongue is foul and coated, the aching in the limbs intolerable, and epistaxis is common. The febrile catarrhs of 1940 and other years I should summarize by saying that the chest symptoms were a great deal more and the general symptoms less alarming."

Dr. Pickles raises the interesting question whether "true" influenza may not be a genuine exotic and our recent immunity due to the closure of the Continent. There was an influenza in England in 1803, after the resumption of the war against Bonaparte, but none again during the war, indeed until 1831, but there was no European pandemic either. Dr. Pickles has seen 202 sufferers from chicken-pox and 87 from shingles in ten years, and contributes interesting examples of the interrelation. On May 6, 1937, a young woman began with herpes, and on May 7 a farmer in a distant village. The young woman, a friend of the farmer's wife, was at a sale a fortnight before and invited to tea; probably the farmer was present. On May 12 (Coronation Day) the farmer was present at the village celebrations; two children sickened on May 26 and 27, and a small epidemic of chicken-pox followed, including one sufferer from herpes. Dr. Pickles could trace two cases of diphtheria to an evacuee, but no other major infectious disease; impetigo, vermin, and scabies were the chief enemies. There were several instances of scabies in native children in homes where there were no evacuees; he thinks common towels in the schools were responsible. One is tempted to go on quoting from this charming paper. Dr. Pickles is happy in his work and his opportunities of contributing new and exact observations on the natural history of disease.

HEPARIN IN PRACTICE

The Scandinavian school of medicine has consistently pioneered the use of heparin, and a symposium[1] on heparin and thrombosis was held in Stockholm in December, 1940. Heparin must be given intravenously. The dosage by intravenous drip to maintain the coagulation time at three times the normal, which is the desirable level for most surgical purposes, is approximately 20 mg. per hour. The dose varies, however, with the condition of the patient, and more heparin will be necessary to raise the coagulation time to a given level after operation than before. To avoid the inconvenience of an intravenous drip and the danger of overloading the heart and the kidneys with excess fluid, some workers have preferred to give four separate intravenous injections of heparin a day, a typical dosage being 75+75+75+125 mg. daily. A further development is Olovson's heparin needle, which is designed to remain in the vein. It has a detachable cap with a rubber membrane, through which the injections can be repeated every four to six hours. Although heparin prolongs the coagulation time, it does not affect the bleeding time, and it can safely be given before or during operations in vascular surgery, such as embolectomy, without increasing the bleeding at operation. On the other hand, there is a very real risk of reactionary bleeding after heparin, and, with the exception of a few special cases, heparin should rarely be administered earlier than four hours after operation. These findings support the hypothesis of Macfarlane[2] that the immediate cessation of bleeding is brought about by capillary contraction, and that coagulation then seals the wound so that bleeding does not recur when the capillaries relax. Heparin has been used chiefly as a prophylactic against thrombosis after operation. The minimum duration for effective treatment is probably until normal temperature and power of movement have returned and the patient can leave his bed. Forty-eight hours has been proved to be too short, and it is doubtful whether the four days recommended by other workers is long enough. Results have been encouraging, though, on the one hand, heparin has been confined to special cases and, on the other, there has been a fall in the incidence of thrombosis even in untreated cases. Emboli large enough to endanger life can form only in the lower limbs, and Bauer has developed a technique to visualize the veins in the leg by radiographs after the injection of perabrodil. Absence of contrast in the deep veins provides evidence of the presence of a thrombus, and measures can be taken to deal with it before embolism occurs. In established embolism and thrombosis heparin treatment is on a less secure basis, though favourable results have been attributed to it in preventing the extension of the clot. Owing to the large amount of kinase released at the lesion, the therapeutic or medical dosage of heparin is very much greater than the prophylactic or surgical dosage, and the risk of accidents is proportionately increased. Haemorrhage and cardiac tamponade have occurred when heparin was administered in pericarditis, and for this reason the physician may well hesitate to use heparin in coronary thrombosis. In fact, a good deal of careful and controlled work remains to be done before we can assess the value of heparin in treatment. At present a manifest post-operative thrombosis means five to six weeks longer in hospital, and a reduction would be welcomed not only by the surgeon but also by the patient, who usually finds this unexpected setback so tedious and hard to bear.

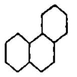
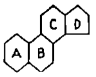
THE STEROLS, THEIR STRUCTURE AND ACTION

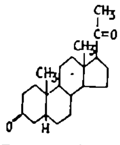
A study of the correlation between the chemical structure and the pharmacological action of a group of compounds may suggest further modifications by which the potency may be enhanced or unwanted side-actions eliminated. Experience has emphasized the wisdom of a cautious estimate of the value of such correlations unless they are made on a very large number of similar compounds, and perhaps in no other field has the relation between structure and function been more obscure than among the sterols. Hans Selye[1] has endeavoured to produce some order out of this chaos by a study of 75 of the hormonally active sterols and their synthetic analogues, together with a very considerable survey of the literature. The importance of the phenanthrene derivatives is shown by the fact that narcotics of the morphine group, bile acids and cholesterol, vitamin D, the sterol hormones, and many carcinogenic hydrocarbons have a phenanthrene nucleus. The subgroup which comprises the sterols consists of modifications of the cholane ring. Selye observed the effect of these modifications upon six different types of action, which he calls folliculoid, corticoid, luteoid, testoid, gonadotrophic, and anaesthetic, and which are independent of one another He distinguishes between such independent actions and subordinate ones: for instance, all folliculoid hormones can stimulate the development of female secondary sex characteristics, causing enlargement of the uterus and breasts, and hypertrophy of the adrenal cortex as well as vaginal cornification. But any one of the six independent activities may be exhibited by a compound, irrespective of its other hormonal properties. Thus pregnanedione has the highest anaesthetic potency yet found, but is devoid of other activity. All sterols with a side-chain of two or less C atoms have some activity, either anaesthetic or hormonal, but the long side-chain derivatives are inert, so far as they have been studied. The commonest pharmacological actions are the anaesthetic and folliculoid, and in fact all but three of the sterols investigated showed some degree of folliculoid activity provided there was not a long side-chain. So the folliculoid and anaesthetic activities do not depend on any great specialization of structure. But the anaesthetic activity may be modified by changes in structure. In the simplest instance this may be due to changes in solubility. Oestradiol has some anaesthetic potency, but its esters, which are more slowly absorbed, have none. Oxygenation, if at either end of the molecule only, increases the anaesthetic effect, but further oxygenation is detrimental. Thus desoxycorticosterone acetate is more active than dehydrocorticosterone. A single double bond in ring A or B does not seriously interfere with the anaesthetic activity, but two or more double bonds in these rings or a double bond in ring D are detrimental. Thus pregnanedione, which is fully saturated, is slightly more active than progesterone, while oestradiol, which has an unsaturated A ring, is inactive. Two chrysopregnene derivatives, with a 6-membered D ring, were also studied, and were found to have both anaesthetic and follicular activity; so evidently the sterol nucleus may be modified slightly without interference with its characteristic properties. But it is more disturbing to find that stilboestrol, which bears no immediate relationship to the phenanthrene group, has an anaesthetic as well as its well-known folliculoid property. It may be that we are dealing here with a member of an entirely different series of compounds, and it would therefore be illogical to apply to it the general laws which have been deduced from a study of the sterols. Further investigation of the stilbene series as well of the sterols may well repay the labour, and emphasize the close association that is now required between the pharmacologist and the organic chemist.



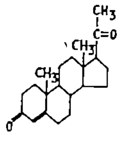
Phenanthrene ring



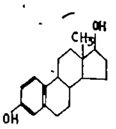
Sterol ring



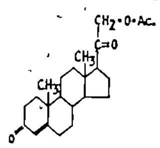
Pregnanedione



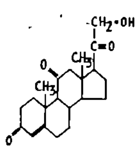
Progesterone



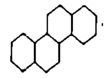
α-Oestradiol



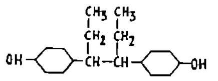
Desoxycorticosterone acetate



Dehydrocorticosterone



Chrysopregnene ring



Stilboestrol

At the invitation of the Managers of the Royal Institution, Sir Henry Dale, P.R.S., has accepted the Directorship of the Laboratories of the Institution, with the Fullerian Professorship, in succession to the late Sir William Bragg. Sir Henry has expressed the wish that his appointment should be limited to a period of three years, so that the Managers may then be free to consider their future policy.

War Medicine Series

The paper printed below is based on a lecture which was one of a series recently given at the British Postgraduate Medical School, Hammersmith

MALARIA IN WARTIME

BY

Sir P. H. MANSON-BAHR, C.M.G., D.S.O., M.D., F.R.C.P.

Malaria in wartime is a large subject, and may be a serious problem. It was so in the war of 1914-18 and probably it will play a part in the present conflict. Then, in the "side shows"—Iraq, Salonika, East Africa, and Palestine—malaria may be said to have been decisive—much more so than enemy action. The admission rates to hospitals which were published in the *Medical History of the War* give impressive figures. In the East African Expeditionary Force there were annually more hospital admissions than troops in the field; that for Salonika was 500 or 600 per thousand troops. Therefore it behoves us more than ever to try to keep in mind what malaria may be like in a war of movement.

There are four different species of intracorpuscular parasites causing malaria, but only two are really important in war; the others do not really matter, just being curiosities. The first causes benign tertian; the second, which may be predominantly important, causes subtertian or malignant malaria.

Unfortunately, scientists have given these parasites many names. I need not bother you with the scientific terms, but I should like to point out how the parasites differ, and how the fevers which they produce also can be distinguished from one another, for there is no doubt that different parasites produce different clinical types of disease. It is of no use at the present time saying that someone has got malaria, and leaving it at that. Research has shown that these fevers differ considerably not only in their clinical appearances but in their treatment also.

The Benign Tertian Parasite

First we have the benign tertian parasite. The ring form becomes attached to the blood corpuscles and then enters them, gradually occupying the whole; but the host cell enlarges when the parasite attains its maximum development as the sporulating form. Moreover, within the substance of the red cell there is produced a degeneration of the protoplasm known as Schüffner's dots, which are peculiar to this and to the *ovale* parasite alone.

Multiple infections of the corpuscle by more than one parasite are rare in benign tertian, although common in subtertian malaria. The sporulating body consists of eighteen to twenty-four spores, and breaks up and sheds the spores (merozoites) into the plasma. It is at this stage that the malaria rigor, or fever, takes place. In the case of the benign tertian parasite this recurs every forty-eight hours. There is another stage, the gametocyte or sexual form, in which the development runs parallel with the former, or asexual, cycle.

There is nothing else quite like a chart showing the classical appearances of the fever. Rigors recur on alternate days at exactly the same time. If the rigor began at 2 p.m. on one day the second rigor will also take place at the same time within forty-eight hours. It was Manson who suggested that any fever which began in the forenoon or early afternoon was more likely to be malaria than anything, more especially if it started with explosive suddenness. The classical features of a malaria attack are the cold, the hot, and the sweating stage, the last taking place when the temperature begins to fall. It is possible to get temperatures of considerable height—104°, 105°, or even sometimes 106° F. When a temperature suddenly shoots upwards so as to cause alarm it is much more likely to be benign tertian malaria than any other kind of fever. Moreover, it falls as abruptly, and afterwards drops to subnormal. The reaction to quinine given intramuscularly may be dramatic, but a subsequent attack cannot be prevented or aborted by one injection of this specific. It just depends upon the stage of development the parasites have attained when the quinine is given whether any further rigors take place.

The classical tertian periodicity is not observed in every case of benign tertian. One must expect fevers, especially in primary infections, which are atypical, resembling tuberculosis or typhoid. Quotidian rigors were formerly held to be due to two generations of parasites running concurrently, but that is not really the case. Rather they are due to the response of the body to a primary infection, because we now know that in experimentally produced malaria we do not get the typical tertian periodicity till the fever has lasted several weeks.

Subtertian Malaria

Benign tertian malaria may be likened to the ordinary rifle bullet, whereas subtertian (*Plasmodium falciparum*) may be likened to a high-explosive shell. The illness the latter produces is different; that is why it is misleading to use the term "malaria" as embracing all these diseases. This parasite does not enlarge the red blood corpuscle in which it lives; and, again, owing to some adhesive properties in the infected corpuscles, they tend to agglomerate, so that development mostly proceeds in the capillaries of the internal organs, and thus the parasite does not freely circulate in the peripheral blood as does the benign tertian. By taking blood slides from the finger one cannot see the complete cycle of development of this parasite in human blood, because a number of stages develop in the sinuses of the spleen, pancreas, brain, intestinal capillaries, and other internal organs of the body. The clinical appearances of the fever depend upon in which organ the maximum multiplication takes place. There is no more protean infection than subtertian malaria. It is a sort of conjurer, continually producing new tricks out of the hat. The parasite at the start somewhat resembles a very small flattened signet ring; next we find it plastered on to the edge of the blood corpuscle, and multiple infections of the cell are common. Irregularity in outline of the corpuscle will be observed, and there are differences in the staining properties of its protoplasm. The sporulating stage takes place almost entirely within the internal capillary vessels; the affected corpuscles agglutinate, forming thrombi, and in the security of their retreat the sporulating form develops. When this last stage is seen in the peripheral blood prognosis is grave, because it means that the patient has been overwhelmed with this parasite.

I will now describe what a blood film looks like in fatal cases such as were frequently encountered during the last war. We see here rapid multiplication of the parasite inside the red cell, and the two bifid nodules of chromatin which usually indicate a severe infection. We can see also large hyaline mononuclear cells which devour defunct malaria parasites. Thus one often finds in subtertian malaria pigmented corpuscles, and nearly always they are mononuclears.

With the subtertian parasite we do not get any dots in the protoplasm of the red cells, but little fissures or holes, which are known as Maurer's dots, or clefts, and they are distinctive.

With regard to the fever, subtertian malaria usually has a quotidian periodicity, but may produce almost any variety of temperature chart. Every now and again there is a sudden drop in temperature, and then it rises once again. In the benign tertian one may see what may be termed a "Salisbury Cathedral" type of chart, but in this case one frequently observes a double rise of temperature—that is, with a dicrotic notch. That is a very important point, and when you see a temperature chart of this description you should always think of this kind of malaria.

I mention this because many years ago I was summoned to a nursing home in London to see a young official who had travelled from West Africa via Barcelona and Paris. There he had partaken of oysters, and was overcome by vomiting and diarrhoea with grave weakness which had been diagnosed as "food-poisoning." With this diagnosis he arrived in London, and there, every day for three weeks, he produced rigors with a double crisis. He had been examined by several doctors and as many diagnoses had been suggested, till a blood culture was taken, and on a streptococcus being isolated he was given the appropriate serum; but still he did not improve. When I was called in I suggested that he must have malaria, to which the objection was raised that he had no enlarged spleen (but many cases of subtertian malaria do not exhibit this) and that no malaria parasites had been found in his blood. I was informed that thirteen blood examinations had been made already and therefore it was no help to suggest malaria. But in the first blood film I was able to demonstrate three parasites within one corpuscle. He took quinine and atebrin that night, and the fever defervesced and soon he was quite well.

Another curious feature of the subtertian malaria chart is that you may not get any fever at all. It is possible to find people in apparent perfect health walking about with this parasite in their blood, and many return from West Africa with this parasite lying dormant, ready to spring into activity and produce the most dire symptoms at the first opportunity on exposure to cold or exertion.

The Mosquito Problem

Now we come to the mosquito problem. What is an Anopheles, and what are you to do when you see one? The first characteristic of the Anopheles mosquito is its posture; it is said to stand on its head. Actually it does appear to stand in this uncomfortable position with abdomen raised in the air, while all other kinds of mosquito carry it in a horizontal position. This mosquito is usually found in nooks and crannies of the wall and ceiling. In wartime it can be discovered inside canvas tents, and whenever you see an Anopheles mosquito the best thing to do is to "swat" it. There are all sorts of minor marks of differentiation between this and other species. The egg of the Anopheles is one of the wonders of Nature. It resembles a primitive float, and, unlike those of other species, is laid singly. The larva on emerging lies with its body parallel to the surface of the water and has a short respiratory siphon. The Anopheles also has spotted wings, whereas other species generally have not, as exemplified by Ross's provisional description, "the dappled-wing mosquito." Several species of Anopheles in Great Britain have been described; indeed, there are probably just about as many individuals of this genus in Great Britain at the present time as ever, so that it is difficult to know why endemic malaria disappeared from this country. But there are different races even of the same species. Some prefer feeding on cattle or horses, others on humans; and it is only those which prefer biting human beings to biting cattle that are dangerous to man.

Next the elaborate cycle inside the mosquito's stomach must be considered; this, as is well known, was worked out by Ross at the instigation of Patrick Manson. It must always be insisted that had it not been for Manson's original hypothesis this would probably not have been worked out at that time. The copulation of the sexual forms of the parasite takes place inside the stomach cavity of the mosquito, and is known as the sexual cycle. Manson's original hypothesis was that there must be one particular type of mosquito, in which this took place; so that time and further work have not upset that original idea—that is, it is only in the genus *Anopheles* that this development may occur.

We have drugs which act upon this parasite in various stages. There are drugs which act upon the sporozoites from the salivary glands and others which act upon the sexual cycle, so that it is becoming more and more important that we should know of these researches because we may in that way eventually find the ideal malaria prophylactic. It is quite obvious that quinine does not fulfil this ideal, because it has been found to have no effect on the sexual cycle and has no influence on the sporozoites. On the other hand, there is plasmoquine, which, although it may not produce such startling results in man, can knock out sporozoites and destroy the sexual stages of the parasites. Then there is atebrin (quinacrine or mepacrine), which acts mainly upon one species (the subtertian), so that we have selective drugs for different stages of malaria parasites.

The Incubation Period

One of the great difficulties in studying malaria is the varying length of the incubation period. In benign tertian malaria it is not unusual for this fever to commence one year to fifteen months after the primary infection; therefore, one commonly meets patients who have been in India and have not had fever there, yet who a year or fifteen months after their return fall sick with an abrupt attack which proves to be malaria.

How long can the malaria parasite persist in the body? The old soldier will assert that he can feel malaria "in his bones." His colonel avers that the only thing is to "drown" it with whisky; he is convinced that he still has malaria thirty or forty years after quitting the Tropics. Are we to believe these stories? I say distinctly they are not true. The parasites have their limited cycle in the body of man. They have their life span just as any other creature. The shortest for subtertian malaria is one year: that of benign tertian is from three to three and a half years at the maximum. The statistics of the Ministry of Pensions show that the benign tertian malaria parasite disappeared within three years from the end of the last war. The quartan parasite is the toughest, because apparently it can hang about in the blood for a very long time. A fatal case was recently reported in London in a child transfused with blood from its father, who had quitted Ceylon twelve years previously. One German observer has even discovered it in the blood nineteen years after primary infection. How are we to explain these long latent periods?

The theory has been developed, backed up by some evidence, that sporozoites do not all immediately enter red blood corpuscles, but lie dormant in the skin, and then infiltrate into the blood stream from time to time, causing malaria. That is a plausible explanation, and may indeed be true.

The Sexual Stage

Next we must briefly consider the sexual stage of the subtertian parasite, or crescent. This looks like a miniature Zeppelin developing inside the red cell, the free edge of which may be clearly visible. It is the black pigment within the parasite that attracts attention, and it was really due to this that the malaria parasite was discovered by Laveran in 1880. While watching one of these parasites, then thought to be dead pigmented cells, he found that when the crescent was abstracted from the blood stream and chilled it underwent an amazing transformation known as exflagellation. This is really a sexual process, and it was due to Manson's explanation of this phenomenon that it was discovered to be a vital process in the life of the parasite. It is not, indeed, as formerly thought, a sort of swan-song of the malaria parasite; but from this amazing act the whole scheme of development of the malaria parasite in the mosquito was formulated.

There are two varieties of crescent—male and female. The latter simply becomes rounded off into a sphere, but the former becomes transformed into this flagellated body. It was Manson, too, who first demonstrated that the flagella broke away, abandoning the defunct body of the parasite, and that each flagellum had a definite structure; but it was McCallum who in 1897 saw the free flagellum impregnating the female. Thus was a vital stage in the elucidation of the life history of the malaria parasite demonstrated.

(*This paper will be concluded in next week's issue.*)

The National A.R.P. Co-ordinating Committee is arranging a one-day conference at Caxton Hall, Westminster, S.W., on Sunday, Oct. 25, starting at 10 a.m. There will be two parallel sets of lectures—one on organizational topics, including post-raid welfare and war damage, and one on more technical subjects, including anti-gas measures, fire defence, casualty services, and industrial defence. There will also be a show of the latest civil defence films from the Ministry of Information. The speakers include Prof. J. B. S. Haldane, F.R.S., Prof. J. R. Marrack, M.D., and Dr. K. W. C. Sinclair Loutit, former A.R.P. medical officer for Finsbury. Inquiries and applications should be sent to the Conference Secretary, A.R.P. Co-ordinating Committee, Faraday House, 8, Charing Cross Road, London, W.C.2.

TOWARDS CO-ORDINATION OF HOSPITAL SERVICES

The Nuffield Provincial Hospitals Trust and the Ministry of Health are collaborating in surveys, region by region, of the hospital services of England and Wales, and in due course the whole country will be covered. For some months past a survey in London and the surrounding area has been in the hands of Dr. A. M. H. Gray, president of the Royal Society of Medicine, and Dr. A. Topping, deputy medical officer of health of the London County Council, and another in North-West England and North Wales, for which Mr. Rock Carling, senior surgeon to Westminster Hospital, and Dr. T. S. McIntosh, one of the principal regional medical officers of the Ministry of Health, are responsible. More recently Prof. J. A. Ryle, Regius Professor of Physic at Cambridge, and Dr. A. E. Quine, another principal regional medical officer, were appointed to undertake a survey in North-East England. The announcement is now made that a fourth survey, to embrace the greater part of the three Ridings, is to be carried out by Mr. H. L. Eason, president of the General Medical Council, Dr. Veitch Clark, lately medical officer of health for Manchester, and Mr. W. H. Harper, house governor of Wolverhampton Royal Hospital. The survey of yet another large region is expected to begin shortly.

In a recent speech at Oxford, made under the auspices of the Nuffield Trust, the Minister of Health, Mr. Ernest Brown, discussed these surveys and the part they will play in the future co-ordination of hospital services. Inquiries of the kind now proceeding, he said, in the hands of experts of such distinction and experience, and based upon free and informal discussions with those who were tackling in different areas the problem of hospital organization, were more promising than any other course which could have suggested itself. They were designed to promote local consideration of problems having more than a local bearing and to encourage friendly co-operation in their solution. The object of the surveys was not to provide working drawings, but to set up a rich fund of knowledge and experience of which those who would presently have the task of producing such drawings might freely make use.

Object of the Surveys

The surveys will be directed in the first place towards obtaining information about existing facilities, their adequacy and efficiency. The starting-point of all inquiries and planning, said Mr. Brown, must be the needs of the patient. Inquiry will be made into the number and types of beds, the adequacy of the consultative out-patient departments, the range of equipment available, the nature and number of the medical and other professional staff, and the service areas of the hospitals. Other questions, such as methods of administration and accounting, purchase of supplies, record keeping, social work, and, most important of all, finance, will also call for consideration, but these are not relevant to the immediate objects in view.

The facts having been ascertained, those responsible for the surveys will formulate their opinions and advice. In the Minister's view the facts which had been elicited should have general publicity, but the conclusions based upon them, the recommendations issuing from them, should be treated as strictly confidential to the Ministry and the Nuffield Trust. What both the Ministry and the Trust desired was a full and frank report, not a report written with the constraint which was necessarily imposed in the case of a public document. Mr. Brown was explicit as to the procedure to be followed after the reports of the experts had been received by the Ministry and by the special committee of the Trust. Certain general conclusions would be formulated, together with the facts upon which they were based, and these would be laid before local authorities and the governing bodies of voluntary hospitals in each area for their full consideration, both separately and jointly. There would be no question of imposing a ready-made plan or of requiring local action to be taken in accordance with the conclusions emerging from the Minister's consideration of the reports.

The Minister anticipated, however, that in due course legislation would be necessary to give effect to the Government's policy of laying upon the major local authorities, in full consultation with the voluntary bodies concerned, a statutory duty to provide an adequate hospital service. In his speech at Oxford he promised, in the most categorical terms, that that projected legislation would be the subject of the fullest consultation with "all interested parties" before it was introduced into Parliament. The medical profession will welcome and bear in mind Mr. Brown's undertaking. It is to be assumed that it means that the results of the consultation will be available, not merely to amend any measure during its passage through Parliament, but to influence the preliminary drafting of it. It would also be desirable that sufficient time should be given for this consultation to enable representative bodies concerned to gather as wide an opinion as possible from their constituents, so that this legislation, which will be of the first importance to the health of the country, may go forward with the fullest measure of agreement.

Reports of Societies

EARLY DIAGNOSIS OF PHTHISIS

The first Varrier-Jones Memorial Lecture, on the early diagnosis of pulmonary tuberculosis, was delivered under the auspices of the Halton Medical Society by Wing-Commander R. R. **Trail** at Princess Mary's R.A.F. Hospital, Halton, on Sept. 25. Air-Marshal Sir **Harold Whittingham**, Director-General of Medical Services, R.A.F., presided, and, before the lecture was given, Sir **Walter Langdon-Brown** spoke on "Varrier-Jones: the Man and the Idea." The late Sir Pendrill Varrier-Jones was Medical Director of Papworth Village Settlement from its inception until his death in January, 1941. Concluding his tribute Sir Walter said: "Rehabilitation is a word on all our lips to-day, and here it is in being. All honour to the man who achieved this and converted occupational therapy into therapeutic occupation. With tuberculosis again increasing its inroads we may well reflect on this vision that became fact."

Wing-Commander **Trail** said that except in a disappointingly small percentage of cases we were a very long way from the diagnosis of early pulmonary tuberculosis, and had no cause for complacency. Progress in combating the disease had been made in certain directions during the past 20 years, but detailed analysis of the position to-day in respect of the number of sufferers and the extent of the disease at diagnosis was not so pleasant. Tuberculosis now claimed half the total deaths from all causes at ages between 15 and 24, an age group particularly important in national economy and the one in which the decline in mortality had continued at a slower rate than in any other. The lecturer then quoted L.C.C. figures showing that the best possible tuberculosis services with every modern equipment made no improvement towards earlier diagnosis in ten years, and added that by the extent of disease at diagnosis the majority of these unfortunates were unsuitable for modern methods of treatment and but few survived for 5 years following discharge from sanatorium. They showed a poor economic return and a minimal gain in social happiness for the care and expense afforded them. He attributed this state of affairs to the fact that it was only with the arrival of symptoms, and not always then, that the patient would seek advice. To ask the general practitioner, therefore, to diagnose at a stage prior to the symptoms for which his advice was eventually sought was to ask the impossible. Experience showed that by no means all cases of established phthisis had symptoms, and doctors had perforce to wait until the patient sought advice. Even then diagnosis was often too long delayed.

Mass Radiographs: Figures from the R.A.F.

After reviewing clinical methods whereby indications of tuberculosis could be detected, the lecturer referred to the value of x rays. "We have in x-ray examination something quite definite to the expert eye, something which, even at its lowest valuation, is a visual indication of abnormality calling for immediate and strict investigation. In other words we have to hand a method of approach to diagnosis which can reverse the present one. The doctor can seek out the patient. He need not wait until the patient seeks him." He then quoted figures derived from the examination of 40,119 R.A.F. and W.A.A.F. personnel by mass radiography. While the miniature film could weed the abnormal from the normal, for ultimate diagnosis a large film and full clinical and pathological examination were necessary whenever an abnormality was noted. This procedure had been followed in all the cases reported upon, and no case had been considered tuberculous where there was any reasonable doubt of the diagnosis as judged by accepted modern criteria. Despite this, and notwithstanding that all these 40,119 persons had been examined by National Service Boards some six to twelve months preceding mass radiography, and that all the men concerned had had a stricter medical examination within the previous six months with a view to selection for special duties, the results of the examination of these unusually "fit" subjects showed that 65 (or 2.2 per mille) of the 30,130 men exhibited signs of active disease, and that 108 (or 3.6 per mille) showed signs of inactive disease. In the case of the 9,989 women the figures were even worse: 38 (or 3.8 per mille) were in the active disease class, and 56 (or 5.6 per mille) in the inactive disease class. The highest figures per mille occurred in the age groups up to 25–29; the incidence in women being considerably higher than in men. "While the incidence of active disease is practically 1 per 1,000 more for women at the age group 20–24, the incidence for women under 20 is more than double that for men. . . . Similarly among inactive cases, the incidence of disease in women under 20 is four times as great as among men, and one and a half times as great in the age group 20–24, while the percentages approximate to equal in the age group 25–29."

The figures also showed that among the supposedly healthy adolescent and young adult population between 18 and 24 there were some 3 per mille who had unsuspected active tuberculosis and that more than 1 per mille was a potential source of infection because he had, unknown to himself, a positive sputum. The number of the population in these age groups by the last Census, corrected according to birth rates at the end of the last war, was, for England, Scotland, and Wales together, some five millions. The implication was obvious. In these age groups at the present time there were some 15,000 with unsuspected tuberculosis; all of them required at least expert supervision and advice, and many were in need of treatment for a period that could be determined only by close observation. These figures all related to patients without admitted symptoms, and it was a legitimate conclusion that some 25% more cases were found in the early stages of disease by mass radiography as against the present civilian methods of diagnosis.

Necessary Safeguards

The lecturer gave a warning that before any extension of mass radiography could take place much preparatory work must be done, because the adult worker associated *x*-ray examination with disease, and disease was economic disaster. It would be difficult to impress on him the benefits of early diagnosis. Legislation would have to protect him against victimization, loss of employment, and reduced standards of life for himself and for his family. Present circumstances worked against both the patient and the tuberculosis services; they hindered immediate treatment by worry and they militated against good end-results by compelling the quiescent case to return to employment before arrest of the lesion was attained. Wing-Commander Trail concluded that immediate hopes for the future control and treatment of pulmonary tuberculosis must be based on periodic mass radiography of the adolescent population; anything less comprehensive would fall short of the lessons indicated by the experience he had analysed. If they began now on a scheme of examination at school-leaving age and followed by annual review to the age of 30, those age groups on which morbidity and mortality fall most heavily would be covered. Initial cost would soon be offset by the saving of vast sums of money now spent on hospitalization of advanced cases.

A new medical centre for the United States Navy has been founded at Bethesda, Maryland, at a cost of seven million dollars, and will consist of a hospital, medical and dental schools, and a dispensary.

Correspondence

R.M.B.F. Christmas Gifts

Sir,—It is always with a feeling of hesitation, perhaps of fear, that I address this letter to you at this time of the year; hesitation and fear lest I should fail to state the cause effectively to your readers. But in my 25th year of office as President of the Fund and as an old man myself, may I once more appeal on behalf of old doctors and their loved ones that the Christmas Gifts Fund be continued in 1942. A gift of £2 to each of our beneficiaries on Christmas Day to bring some enjoyment, perhaps warmth or an unaccustomed comfort, to homes where every penny has to be considered, is my desire. Will all friends who have helped me in the past do what they can again this year, and will others come forward as contributors to take the place of those who have had to drop out?

All contributions should be addressed to the Hon. Treasurer, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15, and cheques should be made payable to the Christmas Gifts Fund.—I am, etc.,

Thomas Barlow,
President.

Working for a Salary

Sir,—In his recent presidential address to the B.M.A. (Sept. 26, p. 357) Sir Beckwith Whitehouse is reported to have said that working for a fixed salary eliminates competition, stultifies individual effort, and therefore is a bar to progress. If Sir Beckwith had contented himself with saying that working for a fixed salary had always been distasteful to him there would have been nothing more to say about it, for *de gustibus non est disputandum*, but he went on to generalize in terms which the facts do not support, and I shall, if you allow me, call evidence to controvert him and to prove that the glitter of gold and the size of one's practice are not the only incentives to honest effort, and that working for a fixed salary need only eliminate competition whose results are as likely to be harmful as beneficial, need not stultify individual effort, and need not be a bar to progress.

Many years ago in a pathology class my fellow students and I sat enthralled while our professor told us the story—and what a story it is—of the four American army doctors, Agramonte, Lazear, Carroll, and Reed, whose courageous and self-sacrificing experiments proved the mosquito transmission of yellow fever and led to a great victory over that disease. These men were working for a fixed salary and were without Sir Beckwith's stimulus of competition, but will he say that their effort was stultified? A few years earlier Major Ronald Ross of the Indian Medical Service, encouraged only by Sir Patrick Manson and spurred on not by the hope of a fatter bank balance but rather by whatever it is that not rarely

> "the clear spirit doth raise
> to scorn delights and live laborious days,"

was fighting a hard battle against official obstruction, the heat of an Indian summer, and other difficulties such as a lack of literature and unfamiliarity with the technique of mosquito dissection, and he did not cease to fight until he had shown that malaria is transmitted by the anopheline mosquito and had charted yet another of the ways of "million-murdering death." Stultification of effort indeed!

A colleague of my own has had sleeping-sickness four times. I shall not name him here as he is a modest man. He had it first as the result of a natural infection contracted in the African bush in the course of his work. It was in the days when treatment was not so sure as it is now, but he made a good recovery. Of the three subsequent infections one was contracted accidentally in the laboratory while handling infected tsetse flies, and the other two were the results of experiments in which he used himself as the laboratory animal in order to find out if certain strains of trypanosomes were pathogenic to man. They were. Three other colleagues allowed themselves to be the subjects of similar experiments, and infected flies were fed on them. Infection followed in one case. All these men had reached the maximum salary in the service to which they belonged, but *pace* Sir Beckwith they were still men of active clinical and inquiring minds, and there is no evidence that their effort was stultified in any way unless someone will say that it was great foolishness to play the part of a rat or a guinea-pig.

Space will only allow me to mention Sir David Bruce (Malta fever and sleeping-sickness), Sir William Leishman (kala-azar), Sir Robert McCarrison (goitre and nutrition), and Sir Leonard Rogers (cholera, amoebiasis, leprosy), all of whom have added greatly to the sum of medical knowledge in spite of the "handicap" of working for a fixed salary.

I shall call no more evidence in support of my case, though I could summon a host of witnesses from unnamed thousands of members of the salaried medical services, whose daily work and achievement would confound Sir Beckwith Whitehouse even more than the evidence I have already called. Hippocrates once said that where there is a love of mankind there also is a love of the art (of medicine), and I contend that both of these are to be found in at least as great a degree among those members of our profession who work for a fixed salary as among those whose work is stimulated by that spirit of competition which Sir Beckwith Whitehouse says is necessary for the best work.—I am, etc.,

London, W.C.1. H. G. CALWELL.

The Non-touch Technique

SIR,—All surgeons, and in particular those of the present "older generation," will be grateful to Mr. H. A. T. Fairbank (Oct. 3, p. 388) for his timely article in especial relation to the making of an incision down on to a fractured bone. It is nothing short of a tragedy to "open" a "closed" fracture and allow infection to occur. To make such a contretemps still less likely it would be well to drop the archaic, in fact silly, expression "simple" fracture as used in the title of and throughout the paper, except once, when Mr. Fairbank uses the accurate and modern term "closed" fracture. It is more than a quarter of a century since "simple" became "closed" and "compound" became "open" in official nomenclature. All will agree that a "simple complicated" fracture reads as a contradiction of terms, but it is just as wrong to state that a "non-touch" operation on a closed fracture makes it a "compound" one when the fracture merely becomes an open one. Dr. Robert Anderson in his letter in the same issue (p. 406) has fallen into a similar error.—I am, etc.,

London, W.1. W. McADAM ECCLES.

Breast-feeding

SIR,—Is it not time that breast-feeding should be considered dispassionately? Breast milk is no doubt good, clean, and cheap. Its perfection depends on the mother's health. It is the best milk for the baby if the mother is passive, calm, and patient, qualities which are not always present and less so now than in peacetime. I dislike Dr. Violet Russell's psychological approach (Sept. 26, p. 377). Surely the feed should not be a sensuous orgy for the infant and a sexual experience for the mother? In Nature, the lamb for instance, with its almost brutal butting of the udder, soon makes one realize that he is going for the food supply pure and simple. We are told by our psychological brethren that the impressions and experiences of infancy may last and colour one's neuroses in later years. Is not keeping a baby suckling at a large pendulous breast up to nine months, when the father may be away on Service during the whole of this time, setting the foundation for a type of child or parental fixation of a not too healthy kind? This is only a random thought, and psychotherapists may be able to tell us whether or not some abnormal behaviours have been modified by breast-feeding.

To say, as Dr. David Gilmour does (p. 378), that breast milk is "far and away the best food he can possibly have" is surely an overstatement. If anything, Prof. McNeil's article (Sept. 5, p. 271) proves to me that doctors in general know so little about infant feeding. How many can work out at once the caloric requirement and scheme of feeding for the classical ten-pound infant? If Nature intended women to feed their young successfully, then they should adopt a more reasonable attitude and go on all fours! Could there be a more awkward position for the suckling babe than the arm of its mother to sit on and a large breast to hold on to? I would plead for common sense. Always advocate breast-feeding and be ready, fortified if necessary with the "alphabet," to talk intelligently about it. But if the doctor considers that from some local or general physical or psychological reason the baby and the mother would fare better on artificial feeding then he should be equally competent to advise. If artificial feeding were such a second-rate thing why are there not more miserable children in doctors' families.—I am, etc.,

Towyn. J. GORDON MATHIAS.

Circulatory Overloading after Rapid Intravenous Injections

SIR,—The letter from Mr. Oswald Tubbs on this subject in your issue of Oct. 3 (p. 406) indicates that Prof. Duval's teaching during the last war has been overlooked.

Mr. Tubbs relates the case of a patient who during an operation for lobectomy was given intravenously a pint of normal saline and 3½ pints of blood. Duval in his advice on the treatment of shock in chest wounds is explicit: "One must always avoid, especially in a case of pulmonary haemorrhage, lowering the head and giving subcutaneous or intravenous injections." He does not in his book *Les Plaies de Guerre du Poumon*[1] explain his reasons. But in conversation he pointed out that the reasons were obvious. The object of an intravenous injection is to improve the systemic circulation. In order that the fluid may reach the left ventricle it must pass through the lungs. If the pulmonary circulation is seriously interfered with by injury the right side of the heart will be overloaded and harm rather than good will result. Duval did not distinguish between a slow and a rapid intravenous injection. Mr. Tubbs has described in detail the ill results which Duval assumed that every surgeon would anticipate.—I am, etc.,

Bristol. J. A. NIXON.

Loneliness in Infancy
